Wide bandgap lead-halide perovskite (LHP) materials appear as ideal semiconductor for tandem architectures with silicon bottom cells due to their large absorption coefficient and processing compatibility. However, LHP still suffer from strong degradation issues mostly due film inhomogeneities, pinholes and surface and electronic grain boundary defects. The most successful strategies to passivate crystalline defects in LHP include non-stoichiometric passivatio filling halide vacancies by anio physical passivation, dimensional engineering with 2D or 1D heterojunctions and passivation with cross-linking agents. Herein, we demonstrate an LHP passivation strategy based on the formation of an ionic polymeric network obtained by thermal-induced. In the developed process, an ionic monomer is deposited on the surface of perovskite surface after thermal annealing. This precursor upon heating undergoes a polymerization reaction forming a cross-linking polymeric network that, simultaneously, passives defects at the grain boundaries and on the surface of the perovskite film. Using a perovskite composition Cs0.85DMA0.15Pb0.9Sn0.1I3 (Eg = 1.64 eV) optimized for tandem applications three different styryl terminated monomers were evaluated. All monomers presented strong perovskite passivation effect enormously increasing the environmental stability without altering the semiconductor bandgap, morphology and absorption spectrum.

2D organic-inorganic hybrid perovskite structures are attractive soft crystalline materials to be used in optoelectronic devices, such as photovoltaics (PVs) and light-emitting diodes (LEDs), mainly due to their capability to improve devices stability against open environmental conditions (humidity and oxidative atmosphere) and the formation of quantum well (QW) electronic structures [1]. In particular, lead-halide Ruddlesden-Popper phases (RPs) are great candidates to achieve such optoelectronic features and, at the same time, protect them from humidity, increasing perovskite stability. Herein, we propose a low-cost and straightforward methodology to process butylammonium-based 2D lead-halide perovskite materials for efficient LEDs active layers [2]. The BA_2PbBr_4(blue), and $BA_2[FAPbI_3]PbI_4$(red) RPs were solubilized into acetonitrile and spin-coated as emissive layers (EML) in an ITO|PEDOT:PSS|PVK|2D-RPs|TBPi|LiF|Al LED structure. Time-resolved and steady-state photoluminescence experiments, combined with atomic force microscopy and structural studies of the RPs thin-films over poly(N-vinylcarbazole) PVK, revealed important insights into the morphology, charge-carrier dynamics, energy, and charge transfer from PVK polymer to the RPs layer The LEDs exhibited a roll-off with brightness and EQE values around 1300 cd $m^{-2}$and 4 %, respectively. This new synthetic route, combined with simple solution-processable tools, allows obtaining high-color purity, low-cost, and functional 2D-perovskite LEDs opening further frameworks for using such kinds of perovskite materials as new active matrixes for optoelectronic devices

Ultrasmall quantum dots (USQDs) are rarely reported in the literature, they have s smaller than 5 nm, excellent optical properties and good biocompatibility. A not analyzed effect in USQDs is photocurrent. Photocurrent occurs when photons are exposed with energy large than the band gap, thus producing charge carriers. With a built-in field or an externally applied bias, these charge carriers can be separated, thus producing a photocurrent in an external circuit. Here we use two types of USQDs, one CdSe (1ST) and another CdSe/CdS core/shell (9S), to analyze photocurrent effects not seen before in USQDs. We used the Raman spectrum to confirm the presence or absence of the shell. The photocurrent effect in USQDs 1ST showed the pattern photocurrent effect for semiconductor materials. Turning on the light the sample had a rise time of 1.26 s and when the light was turned off, it had a decay time of 0.70 s, with the maximum current value being 12.90 pA. However, the 9S sample showed an overshoot when the light is turned off. This effect is related to the accumulation of charge carriers that appear when QDs are subjected to an electric field and the presence of light, this accumulation caused by the potential barrier formed by the shell is released when the light is turned off. When the light is turned on, its rise time is 2.28 s, when the light is turned off, the decay time is 2.59 s, with a maximum current value of 70.51 pA.

Pressure-induced Changes in Optical and Structural Properties of 2D and 3D Halide Perovskites for Energy Conversion Technologies

Hybrid organic-inorganic halide perovskites and their low 2D dimensional counterpart have attracted great attention due to their outstanding optoelectronic properties. These compounds can be used for light emitting and solar cell devices. Coupling between electrical and optical properties leading to high conversion efficiency is close related to crystal distortion. Controlled manipulation of the crystal distortion and compression by external pressure can be a rational route to understanding the relationship among optical, charge transport, and structural properties. Here, we have synthed Ruddlesden-Popper samples ($BA_2(CH_3NH_3)_{n-1}Pb_nI_{3n+1}$) by using N-butylamine (BA) molecules as a spacer for *n*= 1, 2, and 7 (close to a 3D system) and its tridimensional counterpart ($MAPbI_3$, MA= CH_3NH_3) to study the optical and structural evolution under pressure up to ~12 GPa. Optical images showed microplates morphology for 2D samples, unlike 3D, which exhibited cuboid morphology. The photoluminescence of 2D crystals displayed a unique behavior that can be characterized by three distinct regimes when pressure is applied. Initially, these crystals presented a single excitonic peak that is characteristic of its respective n value. However, at intermediate pressures ranging from 1.5 to 8 GPa, the PL peak is splitted into higher photon energy. In the high-pressure regime, the PL emission is completely quenched. Notably, only *n*=7 crystals exhibited complete reversibility after decompression. In contrast, the 3D perovskite exhibits a rapid decline in emission marked by PL quenching when subjected to 3 GPa. Rietveld refinement analysis of the data under pressure are going on and will be correlated to the induced and quenched PL emitting peaks. This study intends to reveal whether the quasi-3D (*n*=7) sample is chemically more stable than MAPbI3 and preserving the charge transport efficiency, which may represent an alternative for use in energy conversion devices.

Slot Die Coating of SnO2 Selective Contacts forPerovskite Solar Cells.

Perovskite solar cells (PSC) are in the spotlight among the energy conversion technologies. Nowadays, n-i-p devices surpass 25% of efficiency and tin oxide (SnO_2) is commonly used as a selective electron transport layers (ETL) [1]. For commercialization, the improvement of stability and the scalability of the devices are current challenges. For commercial production, the deposition of all functional layers needs to be upscalable and, ideally, low-cost and material-efficient. Among the processes, slot-die-coating [2] is very attractive as it allows coating with high-throughput many kinds of materials (including the perovskite layer) using a solution as a precursor and adjusting a few parameters, such as the concentration of the solution, the substrate speed, and the solution pump rate.

In this work, the deposition of SnO_2 by slot-die coating is presented aiming for the application as ETL layer in perovskite solar cells. As a starting point, the same precursor solution as optimized for spin-coated layers were used [3]. The substrate dislocation speed and slot-die head-substrate distance were constant, and the pump rate was changed, aiming to achieve a 30 nm uniform coating of SnO_2. SEM measurements were used to analyze the thickness and morphology. For solar cells devices based on the slot-die coated SnO_2 layers in combination with a FACs-based perovskite absorber were used. J-V scans were performed to evaluate the efficiency and MPP tracking was carried out to test device stability.

Stability of metal contacts to typical processing conditions of perovskite solar cells

Jilian Nei de Freitas[1], Andreia de Morais[1], José Maria Clemente da Silva Filho[2], Francisco das Chagas Marques[2]

[1]Centro de Tecnologia da Informação Renato Archer, [2]Universidade Estadual de Campinas

e-mail: jilian.freitas@cti.gov.br

Charge collection in large-area perovskite solar cells is achieved by using a metallic contact in at least one side of the cell (top or bottom contact), and Ag is often the metal of choice. However, this material suffers from progressive degradation due to reaction with iodide species from the perovskite layer. Thus, the search for a substitute metal that could show adequate cost, conductivity and chemical stability is imperative for the industrialization this technology. Herein, metal grids were deposited by sputtering onto 5x5 cm^2FTO-glass substrates, aiming at their use as front contact in large-are single cells. Different metals were investigated, which were selected based on their current applications in the photovoltaic or electronic industries: Ag, Al, Au, Cu, Mo, Ni, Pd, Pt, Ta. As-deposited grids exhibited good adherence to the substrate, and the lines were continuous, without pinholes, as observed by scanning electron microscopy (SEM) and optical microscopy (OM). Then, the grids were subjected to different steps of a typical perovskite cell assembly procedure: a) cleaning step; b) UV-ozone treatment; c) heating at 180 °C for 1 hour (mimicking the treatments applied for SnO_2ETL deposition); and d) heating at 100 °C for 1h (mimicking the perovskite annealing step). SEM, OM and resistivity data were collected after each step, and after performing a sequence comprising of all 4 steps, which would be used in a complete cell assembly. Afterwards, the stability of the metals when in contact with the SnO_2layer or with direct contact with the perovskite layer, and after accelerated aging tests, was also assessed. The data gathered reveal that most of the metals suffer some sort of degradation in at least one of the conditions investigated, showing that a careful selection of the metal contact is of utmost importance for long-term use of these cells.

[1]Universidade Federal de São João Del Rei (*Departamento de Ciências Naturais*)

e-mail: vitorpfisica@gmail.com

The need for renewable energy sources, with less environmental impact and low cost, has been extensively studied within Materials Science. Alternatives that prove to be effective and capable of large-scale application are sought, with quantum dot-sensitized solar cells (QDSSCs) being a viable alternative [1]. However, for these cells to leave the academic environment and be applied in everyday life, it is necessary to improve stability. Given this context, the focus of this study was to investigate the stability of the CuS counter electrode (CE) in CSSPQs [2]. The CuS CE were deposited by the chemical bath deposition technique. Synthesis and deposition parameters were investigated: reagents concentration, synthesis temperature and post-synthesis treatment. QDSSCs were prepared using CdS quantum dots and characterized through IxV curves and impedance spectroscopy, for 43 days. Degradation mechanisms that reduce the performance of QDSSCs and CuS CE was investigated. Adequate adjustment of the CuS synthesis and deposition parameters were extremely relevant to improve devices stability. Stable devices, for 43 days, was obtained, for CuS deposition in the optimal conditions. The aging study showed that there was a corrosion of CE in the electrolyte and possible diffusion to the photoanode, causing a reduction in the CE electrocatalytic activity and consequently an increase in the CE charge transfer resistance. It was concluded that one of the relevant factors in the QDSSC performance degradation is related to CE charge transfer resistance, due to the CE instabilities. To increase the overall stability of QDSSCs, it is vital to understand the degradation mechanisms in order to prove their reliability.

e-mail: dibeine@gmail.com

In this work, the structural and photophysical stability of MAPI was analyzed (at the MAPI/P3HT interface. Water is the main catalyst for the irreversible degradation of perovskite material, pointing to a problem for the lifetime of these solar cells. The deposition of Poly(3-hexylthiophene) P3HT on the perovskite had the main purpose of providing a form of encapsulation for the MAPI, that is, to prevent the device from being affected by the humidity of the environment causing degradation. The MAPI was deposited on the FTO substrate (fluorine-doped tin oxide) in two rotation steps. Chlorobenzene was used as an antisolvent and after deposition, the sample was heated at a temperature of 100°C until the transition to the crystalline phase occurred. To form the MAPI/P3HT interface, a solution of P3HT diluted in chlorobenzene was deposited on the MAPI by spin-coating. Photoluminescence (PL), UV-vis absorbance, and x-ray diffraction (XRD) measurements were taken over 30 days. Using the x-ray diffraction technique (XRD), we followed the degradation process of the encapsulated sample and the same one without encapsulation, exposed to the same environment, allowing us to analyze the variation in the intensity of the peaks referring to the product of the decomposition reaction, PbI2. The DRX data showed that over the course of 1 month, there was better stability in the MAPI/P3HT interface. The photoluminescence measurements indicate that the excitation and emission bands of the P3HT polymer are different from the characteristic of MAPI, thus we do not have overlapping bands that could decrease photon absorption. Finally, the MAPI/P3HT interface proved to be efficient in terms of stability for future applications in photovoltaic devices.

A sustainable approach to meet the global energy needs require research efforts to improve our energy conversion technologies and reliance on renewable and clean sources. Organic-inorganic halide perovskites solar cells (PSCs) have received great interest in solar energy conversion due to their high efficiency, low exciton binding energies and high light absorption [1]. However, hysteresis phenomena, chemical stability of perovskites exposed to ambient conditions, make their long-term use challenging. Low dimensional materials have attracted a lot of interest due to their fascinating properties and unique structure [1]. As a way to explore the use of these materials and their effects on the properties of the PSCs, MoS2 quantum dots (QDs) have been integrated in the absorber layer of PSCs. The aim of this work was to study perovskite-MoS2 QDs composite films and their atypical alignment of energy levels, forming a type-I heterojunction, which has not yet been extensively explored [2]. A type-I architecture makes it possible to enhance carrier extraction from the QDs and, in general, to exploit synergies between the respective material qualities. A detailed characterization of the composite film materials and film properties through test structures of photovoltaic devices will then be presented. The electronic band structure of the MoS2 QDs and MAPbI3 films has been experimentally determined, using a combination of techniques that revealed the type-I alignment.

Acknowledgment: This work has been supported by CAPES and CNPq.

Abstract: With the rapid development of the world economy and the increase in population, increased energy demand and environmental pollution, which have become challenging problems for sustainable development. In this context, an attractive alternative that has been developed by researchers to produce renewable energy is the quantum dots-sensitized solar cells (QDSSC), which have a theoretical efficiency of ~44% [1]. Quantum Dots (QDs) are colloidal nanocrystalline semiconductors with a diameter ranging from 2 to 15 nm, whose most prominent property is the quantum confinement effect. The synthesis commonly used to produce these QDs occurs in an organic medium. In this work, QDs Cu-In-S_2(CIS) were synthesized via hydrothermal route, considered an economic and ecological alternative in relation to organic syntheses [2]. The choice of CIS QDs was due to their broad visible absorption spectrum (with an appropriate bandgap of ~1.5 eV) and absence of toxic metal such as Cd or Pb. The QDs were applied in the sensitization of photoanodes for solar cells, which efficiency achieved was of 1.37% with a fill factor of 0.46. Based on the results obtained, the hydrothermal synthesis proved to be a simple and green route for the obtention of high-quality nanocrystals for photovoltaic applications. Other synthetic parameters of the CIS QDs will be discussed relating to the efficiency of the solar cells achieved.

Acknowledgments

This work was supported by CNPq, FINEP, CAPES and FAPEMIG.

Lead halide perovskites have been attracted great attention as light emitting materials due to the unique optoelectronic properties such as high photoluminescence quantum yield (PLQY) and long PL lifetime. The fabrication of UV-light emitting device by using this perovskite family with high efficiency can be used in interdisciplinary fields. Nowadays, the biggest challenge is to synthe these materials emitting in the UV region through anion exchange, finite effect, and/or changing dimensionality. The 2D perovskites have recently emerged as a family of more stable materials that present peak emission in the UV region. In this work, 2D halide perovskites of (M)2PbX4 were studied, where M are molecules acting as a spacer between the perovskite layers formed by the confined [PbCl6]4- octahedrons. The inorganic layer shows strong confinement effect enlarging the band gap energy and improving radiative exciton recombination. Here, the strategy used was anion exchange by using I, Br, and Cl in (BA)2PbX4 and using N-butylamine (BA) molecules as spacers. Structural and morphological characterizations indicated that all the 2D perovskites samples were successfully synthed resulting in quantum nanoplatelets. The observed Bragg reflections can be indexed as belonging to an orthorhombic crystal structure with a Pbca space group symmetry. Scanning and transmission electron microscopy show a laminar 2D structure indicating the formation of nanoplateles which have two distributions 9 nm and 36 nm. Photoluminescence measurements reveal emitted photon energy around 3.57 eV for nanoplatelets and E1 = 2.38 eV, E2 = 2.88 eV, and E3 = 3.47 eV for X = I, Br, and Cl, respectively. The (BA)2PbCl4 bulk sample showed a very low PL intensity while quantum nanoplatelets, combining and structural confinements revealed improved UV emission with higher PL quantum yield. We will present a systematic study involving synthesis and physical properties of these 2D UV emitting materials.

Synthesis and Physical Properties Study of 2D Hybrid Perovskites for Energy Conversion

Leonardo José Quintero Da Cuna[1], Aryane Tofanello[2], Jose Antonio Souza[1]

[1]Universidade Federal do ABC (*CCNH*) , [2]Universidade Federal do ABC

e-mail: leonardo.quintero@ufabc.edu.br

Organic-inorganic halide perovskites and their low 2D dimensional counterpart have attracted a lot of attention in the development of new optoelectronic technologies. The two-dimensional Ruddlesden-Popper (RP) perovskites have crystal structure versatility and improved long-term stability when subjected to light, moisture, and thermal stress. These perovskite crystals are structured as n-layer inorganic octahedral sheets, $(OM)_2(CH_3NH_3)_{n-1}Pb_nI_{3n+1}$, sandwiched by two layers of large organic molecules (OM) spacer acting as quantum well barriers. Here, we have synthed RP samples by using N-butylamine (BA) molecules as a spacer $BA_2MA_{n-1}Pb_nI_{3n+1}$ for n = 1, 2, 3, 4 and n = ∞ (3D) and $MA=CH_3NH_3^+$(methylammonium). Powder X-ray diffraction indicated that the samples for n = 1, 2, 3 and 4 crystallizes in an orthorhombic crystalline structure while n = ∞ shows Bragg reflections belonging to a tetragonal structure. Scanning electron microscopy images confirm 2D morphology. They present a laminar structure with the thickness of the samples increasing with the value of n from 5 μm (n=1) to 15.8 μm (n=4). The 3D structures have irregular rounded particles, with an approximate between 25 μm to 60 μm. The quantum confinement effect presented in the octahedral sheets leads to a blue-shifted emission peak. Thus, we have observed an emitted photon energy progressively decreasing from 2.38 eV (n=1) to 1.50 eV (n=∞). Electrical conductivity measurements, with light and without light, as a function the number octahedral sheets are being carried out in order to observe the effect of quantum confinement on the photoinduced charge carriers. The study of the structural, morphological, optical, and electrical properties of these 2D samples will berationalized involving separation and charge transfer processes. Our study may reveal if these 2D systems can represent a possible alternative for use in energy conversion technologies.

Synthesis of High Quality Zn-Cu-In-S/ZnS Quantum Dots and the Ligand Exchange Effects on SensitizedSolar Cell

Letícia Regina de Carvalho Cunha[1], José Agenor Carvalho Júnior[1], Cecília Balduíno da Silva[1], Thais Adriany de Souza Carvalho[1], Marco Antonio Schiavon[1]

[1]Universidade Federal de Sao Joao del-Rei (*Departamento de Ciências Naturais*)

e-mail: leticia-rcc1@hotmail.com

Solar cells have gained increasing interest in recent years, as they represent the most important way of converting sunlight into electricity. Quantum dots sensitized solar cells (QDSSC) have attracted attention due to their low manufacturing cost and high solar energy conversion efficiency [1]. Quantum dots (QDs) are colloidal nanocrystalline semiconductors, the Zn-Cu-In-S (ZCIS) and Zn-Cu-In-S/ZnS (ZCIS/ZnS) QDs stand out for presenting advantages due to high optical absorption coefficients, high quantum yields, greater stability, decrease in surface defects and low toxicity [2]. In order to control the hydrodynamic particle , it is necessary to exchange the surface ligands. In organic syntheses, the most used ligand is dodecanethiol (DDT), whereas to disperse nanoparticles in an aqueous medium, the most used ligands are thioglycolic acid (TGA) and mercaptopropionic acid (MPA). In this work, QDs ZCIS and ZCIS/ZnS were synthed in organic medium and both QDs had their surface modified by exchanging MPA and TGA ligands, in order to achieve stability in aqueous medium. The best result obtained was the cell sensitized with QD CZIS-TGA, obtaining 2.9% efficiency. Based on the results, it was possible to perceive that the ZnS shell hinders the transfer of charge. In relation to the surface ligands, the TGA proved to be more efficient than the MPA, indicating a greater amount of adsorbed QDs due to its reduced .

e-mail: ayala@fisica.ufc.br

Low-dimensional metal halide perovskites (LDMHPs) have captured considerable attention due to their promising optoelectronic properties. The excitons in these materials are strongly confined, resulting in large binding energies due to the significant quantum confinement and reduced dielectric screening. Excitons in LDMHPs can exist in two forms: free exciton polaron (large polaron) or self-trapped exciton (STE) (small polaron). Free excitons display narrow, near-band edge emissions, while STEs are characterized by broad emissions that are tightly localized by lattice distortion.

This study focuses on investigating the photoluminescence (PL) spectra and the exciton-phonon coupling in LDMHPs at varying temperatures. The analysis of the temperature-dependent PL spectra reveals that STEs dominate the low-temperature PL emission, while band-to-band excitons become more prominent at higher temperatures. Additionally, the coupling strength between STEs and phonons is investigated as a function of temperature, leading to a shift in the STE emission.

Our findings provide insight into the coexistence and complex interplay between long- and short-range interactions in LDMHPs, which present significant challenges in understanding and describing exciton behaviors in these materials.

Perovskite solar cell (PSCs) has become a promising photovoltaic technology. Despite achieving a conversion efficiency exceeding 25.5%, reaching 20% remains a significant challenge [1], which reveals the still incomplete knowledge regarding the understanding of performance-limiting mechanisms [2]. Here, we propose a method based on the dark current-voltage (I-V) behavior to evaluate the effect of a PMMA-MXene passivation layer on the PSCs. We also applied it to a simpler Nb_2O_5/PEDOT Schottky diode (SD). The passivation layer was deposited via spin coating between the perovskite film and the ETL in a p-i-n architecture and between the Nb_2O_5film and the PEDOT top electrode in a sandwiched diode structure. We fabricated the PSC following a meticulous protocol under glove box conditions, whereas the Schottky diode was partially fabricated under room conditions. For SDs and PSCs, the passivation layer prevents a portion of the current shunt with a minor drawback in series resistance. We extracted the ideality factor (IF) using analytical methods, in which the SDs exhibited an increase after the addition of the passivation layer (3.2) compared to the control device (2.7). For the PSCs, an initial IF increase after adding the PMMA layer (from 2.7 to 3.7) was followed by a decrease upon the incorporation of the MXene (3.0). This trend was confirmed by the light intensity-dependent open-circuit potential (Voc) analysis, i.e., an IF value shift from 1.9 to 3.0 followed by a decrease to 1.85 after MXene. Therefore, the passivation maintains the benefits of the PMMA layer while providing additional advantages in electron collection due to the MXene. The dark I-V and IF analysis provide insights that may offer a fresh perspective on the analysis and optimization of PSCs.

The Electron Pair Distribution Function (ePDF) for Structural Studies of Cadmium Selenide Quantum Dots

Olavo Fiamencini Verruma[1], João Batista Souza Junior[2], Victor Secco Lemos[3]

e-mail: olavofverruma@gmail.com

Quantum Dots (QDs) like Cadmium Selenide (CdSe) are nanometric semiconductor materials under massive study due to their optical and electronic properties controlled by quantum confinement[1]. Nanoparticle crystallographic structure can hinder the efficiency of QDs applications, mostly due to the concentration of defects such as grain boundaries, stacking faults, and vacancies. The small size nanoparticle of QDs makes it more difficult to characterize the crystallographic structure by standard techniques like X-ray Diffraction. Then, the Pair Distribution Function (PDF) analysis of the total scattering data has beenraised as an alternative method to suppress those problems and solve the atomic arrangement structure for nanomaterials[2]. Alternatively, the PDF from electron diffraction (ePDF) presents itself as an optimal possibility to characterize nanoparticles as the strong electron matter interaction enables the acquiring of diffraction patterns for a known ensemble of nanoparticles, i.e. TEM equipment can collect diffraction by a precise nanoparticle region matching images and elemental composition analysis with ePDF analysis. In this work, CdSe QDs from 1.9 nm to 4.0 nm were synthed by modifying the procedure. A modified code of eRDF Analyzer software was used to calculate the structure factor S(Q) by normalizing the intensity scattering profile I(Q) with the expected atomic scattering factors. The Reduced ePDF G(r) was obtained by the Fourier Transform of S(Q). Simulated I(Q), S(Q), and G(r) for spherical z-CdSe nanoparticles were introduced in the eRDF code to guide the data treatment and extraction of the final G(r). We have seen that G(r) results lead to smaller crystallite compared to TEM morphological diameter and the obtained from the position of the first excitonic peak. Concluding, ePDF G(r) showed to be a good crystallographic tool for semiconductor CdSe QDs analysis.

e-mail: nataliafcoutinho@gmail.com

The current high demand for cheap and renewable energy has given a great deal of support for the development of low cost photovoltaic solar cells. Today the most promising material is the lead-halide perovskite that has achieved efficiencies as high as 25.8% in few years of research. In spite of the incredible efficiency obtained, it faces a problem in stability, apart from having lead, a toxic element. In this way, some lead-free materials have been studied in the last few years, including bismuth triiodide (BiI_3) [1], a semiconductor with a bandgap of 1,67 eV [2], thereby suitable for photovoltaic applications. Here we investigate the thermal stability of thermally evaporated BiI_3thin films annealead up to 150 °C in ambient atmosphere and in the absence of illumination. BiI_3films show similar X-ray diffratrograms with indexed peaks related to an R-3 rhombohedral crystal structure. Tauc plots of transmittance data of BiI_3in UV-vis range indicates a bandgap of 1.72 eV regardless the annealing temperature. BiI_3morphological properties, observed through SEM images, are also not changed regardless the annealing processes. Thereby, the structural, morphological and optical properties of annealing on thermally evaporated $BiI_3$are not considerably altered, the films retaining their properties when heated up to 150 °C. Since this temperature is higher than the operating temperature of solar cells, these results corroborate for the possible photovoltaic application of BiI_3.

Perovskite solar cells (PSCs) are currently one of the most promising technologies for generating clean energy. Despite significant advances in conversion efficiency, PSCs face drawbacks regarding their long-term stability and interfacial defects between perovskite and the associated charge transport layers. Recently, PMMA has been used as passivation layer to bypass PSCs challenges, however, its high resistance has compromised the polymer application[1]. MXene, a new class of 2D material, has shown high conductivity, transmittance and has been successfully applied to PSCs in the last years[2]. In this way, a PMMA passivation layer dopped with Ti_3C_2Tx-MXene was deposited via spin coating between the perovskite and electron transport layer of an inverted PSC. The incorporationof MXene was confirmed by XDR patterns and UV-Vis spectroscopy. FE-SEM images show auniform formation of the passivation layer onto perovskite for all samples. The presence ofthe MXene in the PMMA layer resulted in the increase of PCE (21.9%) when compared topure PMMA (17.6%) based devices. Photo-CELIV measurements showed a substantial increase of charge mobility and density of extracted charges after incorporation of MXenes.The presence of the 2D material also resulted in decrease of the series resistance whereasnegligible difference in PMMA shunt resistance was observed. TPV measurements showedenhanced charge lifetime for the MXene based devices. These results were corroborated bythe decrease of the calculated trap density indicating a defect passivation by PMMA:MXenelayer. Finally, PMMA:MXene based device showed substantial improvement of stability bywithstanding 95% of its original PCE against only 87.5% of the pristine device after 3000hours.

Crystallographic characterization of the mineral zircon and the thermochronology

Carlos Alberto Tello Saenz[1], Murilo Candido de Azevedo[1], Luiz Augusto Stuani Pereira[2]

[1]Universidade Estadual Paulista (*Física*) , [2]Universidade Federal de Campina Grande (*Física*)

e-mail: tello.saenz@unesp.br

The zircon mineral was characterized by SEM and micro-Raman before and after etching to study its crystallographic structure. Through the etching used to reveal the fission tracks is possible to observe crystallographic damage in the zircon grain that may have been acquired during its genesis or throughout its geological history. These imperfections are known in the literature as Metamictization, Leaching and Chemical Differentiation. The zircon grains were classified, after etching, into four groups: Homogeneou Heterogeneous, Hybrid and Anomalous [1]. Based on this classification, new characterization studies of this mineral were carried out showing nine groups. These results were used to obtain zircon grain age data using two methods simultaneous: the Fission Track Method and the U-Pb method. These ages can help to better understand the thermochronology of the geological region where the zircon grains were collected.

Unraveling the Arrhenius Activation Energy for Fission-Track Annealing in minerals

Sandro Guedes de Oliveira[1], Matheus Rufino[1], Arnaldo Luis Lixandrão Filho[1]

[1]Universidade Estadual de Campinas (*Departamento de Raios Cósmicos e Cronologia - Instituto de Física Gleb Wataghin*)

e-mail: sguedes@unicamp.br

Fission-Track Thermochronology (FTT) is a technique used to estimate the thermal histories of minerals and rocks containing uranium, such as apatite, zircon, and epidote. The spontaneous fission of uranium produces two fragments that damage the mineral crystal lattice along their trajectory. At moderate temperatures, these damaged regions, known as fission tracks, are partially restored through annealing. To understand annealing kinetics, mineral samples are heated at varying temperatures and durations. Empirical Arrhenius-type equations are used to relate reduced fission-track length with temperature and duration of heating. These models are extrapolated to the million-year timescale for geological applications [1]. However, current annealing models are purely statistical and do not provide information about specific annealing mechanisms. In this contribution, we present a physicochemical framework that allows us to retrieve the Arrhenius activation energy for annealing mechanisms and derive new models from different combinations of activation energies [2]. This framework has the potential to provide insights into annealing mechanisms and increase the reliability of model extrapolations.

Analysis of phototransferred thermoluminescence inrose quartz

Isabela Alves Ferreira[1,2], Matheus Cavalcanti dos Santos Nunes[3,2], Makaiko Chithambo[4], Neilo Marcos Trindade[2]

[1]Instituto Federal de Educação, Ciência e Tecnologia de São Paulo, [2]Instituto de Física/USP (*Departamento de Física*), [3]Universidade Estadual Paulista (*Departamento de Física*), [4]Rhodes University (*Departament of physics and electronics*)

e-mail: isabela.ferreira@ifsp.edu.br

Due to its luminescent properties, natural quartz is widely studied by stimulated luminescence techniques including thermoluminescence (TL) [1]. TL is a temperature-resolved emission observed from previously irradiated insulators [2]. When some TL glow peaks are removed by heating, it is possible to regenerate them by exposing the sample to light of a specific wavelength for a certain time. This phenomenon is named phototransferred thermoluminescence (PTTL) and occurs because of the transfer of electrons from a deep electron trap to a shallower electron trap, using light [1]. For this study, a powdered rose quartz sample (>75 μm), with mass of 110 mg, was used. PTTL measurements were carried out using a Risø TL/OSL DA-20 luminescence reader. Sample were irradiated to 130 mGy at room temperature using a built-in 90Sr/90Ybeta source. The sample was illuminated using 470 nm blue light for 50 seconds. Before the illumination, the sample presented 5 glow peaks, a prominent glow peak at 76 °C (I) and other glow peaks at115 (II), 180 (III), 290 (IV), 423°C (V). In the PTTL tests with blue light, it was possible toobserve that peak I presented the phenomenon of PTTL. Based on these tests, peak I worksas an electron acceptor and peaks II as the main electron donors for the observed PTTLsignal in peak I. In addition, peak I and II are the main components responsible for the observed rose quartz PTTL.

e-mail: neilotrindade@usp.br

Recently we have studied some luminescent properties of alexandrite (BeAl2O4:Cr3+), quartz (SiO2), and fluorapatite [Ca10(PO4)6F2], using the thermoluminescence (TL) technique. TL corresponds to the light emission upon heating of insulating or semiconducting materials previously exposed to ionizing radiation, besides incandescence [1]. The TL signal was detected with a bialkali PMT behind a UV-transmitting, visible-absorbing glass filter (Hoya U-340, 7.5 mm thick). Irradiation was performed at room temperature using the built-in 90Sr/90Y beta source (dose rate of 10 mGy/s).

Alexandrite showed five TL glow peaks, I (~355K), II (~405K), III (~445K), IV (~530K), and V (~580K), at a heating rate of 1K/s. In this case, peaks IV and V were investigated because they present more useful characteristics for dosimetry. Alexandrite showed good linearity in the TL signal of both peaks as a function of dose (0.5 to 5 Gy). For rose quartz, TL analyses showed an intense glow peak in ~355K, at a heating rate of 1K/s. The TL dose response showed a weak sublinear behavior in the dose range from 0.01-0.1Gy and, after that, a supralinear tendency. In fluorapatite, the TL curve showed three glow peaks located about I (~350K), II (~470K), and III (~570 K), at a heating rate of 1K/s. The dose response, from 1 to 5 Gy, is linear for all TL glow peaks in fluorapatite.

With this work, we expect to have contributed with useful information regarding the use of luminescent properties of minerals for dosimetry purposes.

Effects of radiation on the crystal lattice of minerals: a case study on Zircon and Apatite.

ANTONIO SAID WEBBE SALES[1], Luís Roberto Gentil[1], Sandro Guedes de Oliveira[2], Airton Natanael Coelho Dias[1]

[1]Universidade Federal de São Carlos - Campus Sorocaba (*DFQM*) , [2]Universidade Estadual de Campinas (*IFGW-DRCC*)

e-mail: antonio.sales@estudante.ufscar.br

In this work, micro-Raman spectroscopy characterization [1] of Apatite and Zircon is presented. These minerals are commonly used in geo-thermochronological dating methods such as Fission-Track Thermochronology (FTT), U-Pb and others. Both minerals have some ppm Uranium and Thorium content in their crystal lattices. In this context, the crystal lattice can feel the radiation effects when these atoms fission and/or decay. In view of this, it is important to investigate how these damages interfere with the mechanisms used in the application of FTT (e.g., diffusion kinetics, chemical attack and annealing). Thus, aliquots of these minerals were analyzed under different conditions: i) mineral under natural conditio ii) after total annealing; iii) post-irradiated with high energy ions, and; iv) post irradiation with high energy ions + alpha particles. These conditions are intended to simulate damage to the crystalline lattice by only 238U fission and/or metamictization (lattice destruction due to alpha decay). In zircon case, the spectra show that the irradiated samples (i.e.; ZIR and Ziα) suffered an apparent damage by reducing the intensity and FWHM increase at 1008. On the other hand, the restorative effect of heating to the crystal lattice is perceived by the sample ZAN that presents a greater intensity in relation to the ZST sample. Apatite shows that, at 963 cm-1, the irradiated samples (i.e.; AIRPR and AiαPR) show an increase in the intensity and narrowing of the FWHM. These intensity variations and FWHM indicate the beginning of a phase transition and/or increase of the amorphous phase in relation to the crystalline phase. New characterizations via SAXS and TEM may indicate in more detail how the crystal lattice responds to irradiation.

Investigating the radiation interaction with matter allows one to verify predictions based on theoretical modeling as well as to develop various applications, as those present in nuclear medicine and nanotechnology. When matter is in the solid state, ionizing radiation is able to transfer its energy to the target causing structural modifications. However, the mechanisms responsible for the conversion of the transferred energy to these structural modifications are still on debate in the literature and only a robust experimental database would furnish the means to unfold the most efficient mechanisms for materials with different physical and chemical properties. In this presentation, we address the formation of defects in calcium fluorite crystals irradiated with heavy ions in the electronic regime, focusing on the possible use of fluorescence microscopy. Due to the extremely large band gap, point defects are able to trap electrons and holes. These centers absorb electromagnetic radiation in the visible spectrum and fluoresce [1], providing information concerning the kind of defect, its concentration, and its spatial distribution. Due to the partial radiolysis of the crystals when exposed to radiation, extended defects are associated to metallic colloids and gaseous inclusions [2]. The colloids scatter electromagnetic radiation and induce surface enhanced Raman scattering, providing information concerning their size distribution [3]. We estimate the expected fluorescence signal and present preliminary results.

The potential of natural alexandrite as a dosimeter was investigated because the chemical nature of this mineral, $BeAl_2O_4:Cr^{3+}$, combines the two oxides most commercially used for applications using optically stimulated luminescence (OSL), these being BeO and Al_2O_3. OSL occurs when an insulator or semiconductor is exposed to ionizing radiation and after an optical stimulus, the material emits photons in proportion to the radiation dose given previously [1]. The measurements were carried out using a Risø OSL reader (model DA-20). OSL emission was stimulated using different light-emitting diodes: blue (470 nm), green (525 nm), and infrared (850 nm), in constant wave (CW-OSL) and linear modulation (LM-OSL) mode. Irradiation was done using a built-in $^{90}Sr/^{90}Y$ beta source. The alexandrite powder samples showed a luminescent signal for the dose range from 0.1 to 1Gy for the three different types of LED. The CW-OSL and LM-OSL curves could be mathematically deconvolved into 3 components labeled fast, medium, and slow. The intensity of the curves and consequently of the components was more intense for stimulation with blue LEDs. The dose-response is linear and reproducible for the studied dose range. In general, alexandrite presents promising behavior for applications in the dosimetry field.

Kinetics of chemical etching in isotropic, solid-state nuclear track detectors: Predicting etch-pit diametersof alpha particles from a bulk source

Igor Alencar[1]

[1]Universidade Federal de Santa Catarina (*Departamento de Física*)

e-mail: igor.alencar@ufsc.br

Radiation is essential to life. However, up-to-date it is still not possible to distinguish clearly the safe limit between benefic and malefic effects caused to organic tissue by exposition to ionizing radiation. Particularly, there seems to be an apparent contradiction in utilizing radiation sources for cancer therapy with their potential correlation as a factor responsible for cancer. In this way, it is mandatory to monitor radiation levels, especially in dwellings, where there is a low air circulation. For such purpose, high-resolution, active detectors are not well-suited due to the relatively low radiation activity present. On the contrary, passive nuclear track detectors, based on the processes of registration and revelation of the ionizing radiation trail, are more promising. Generally, these detectors are composed of low cost polymers, which allows a broad evaluation of the activity distribution in a whole geographic region. In order to identify the energy and mass of the nucleus responsible for the track formation, it is crucial to correlate these parameters with the observables after track revelation. Notably, etch-pit diameter is the simplest parameter to quantify and an extensive theoretical modeling has been proposed to its kinetic description [1]. Nevertheless, only the asymptotic behavior has been utilized in the literature. In this work, I present a reappraisal of previous results on alpha spectrometry in poly-allyl-diglycol-carbonate (PADC) using an americium source [2]. The Kolmogorov-Smirnov test is applied as the figure-of-merit for the etching kinetics and an independent prediction for irradiation with a bulk source is compared to experimental results.

Synthesis and thermoluminescence studies of Ce^{3+}doped calcium aluminate

Walace Rodrigues da Silva Júnior[1], Elisabeth Mateus Yoshimura[2], Carina Ulsen[3], Neilo Marcos Trindade[2]

[1]Universidade Estadual Paulista (*Pós-Graduação em Ciência e Tecnologia de Materiais*) , [2]Instituto de Física da Universidade de São Paulo (*Física Nuclear*) , [3]University of São Paulo

e-mail: walace.junior@unesp.br

Calcium aluminate ($CaAl_2O_4$) has full potential to be designed for thermoluminescence (TL) applications like persistence luminescence and dosimetry [1]. Recent studies show that Ce^{3+} can be a good candidate in the $CaAl_2O_4$ matrix for TL applications. TL is a powerful technique used for dosimetry of ionizing radiations. Ce^{3+} doped $CaAl_2O_4$ was prepared by the combustion synthesis method. $Al(NO_3)_3$, $Ca(NO_3)_3$, and urea are used as starting materials. Urea acts as a fuel for combustion and $Ce(NO_3)_3$ provides the doping ions. The mixture of reagents was kept in a conventional furnace at 500ºC for about 5 min. After combustion, the crystalline powder was crushed in a porcelain crucible, then it was annealed at 950ºC for about 2 h. Phase formation was determined by X-ray diffraction (XRD) patterns. XRD pattern of Ce^{3+} doped $CaAl_2O_4$ was collected using an X-ray diffractometer (Panalytical - Empyrean) with a Cu-Kα (λ= 1.5 Å). The X-ray tube was operated at 45 kV and 30 mA. The 2θ degreeswere recorded from 0° to 50° in a 0.02° step. TL measurements were performed with theRisø reader (model DA-20) composed of a beta source $^{90}Sr/^{90}Y$ (dose rate 10mGy/s) used toirradiate the sample and a Hoya U-340 filter (transmission window 290-370 nm). The samplewas irradiated from 0.010 Gy to 1 Gy. The TL glow curves of the samples were deconvolutedusing the TGCD package. In addition, the dose response, reproducibility, and repeatabilitywere studied. XRD analysis showed high crystalline formation of the monoclinic phase. Thesamples show linear dose response of $R^2 = 0.9993$ in the range studied. So far, it can beconcluded from this preliminary study that $CaAl_2O_4:Ce^{3+}$detectors have potential for applications as dosimeters.

Whey-assisted proteic sol-gel method as a newsynthesis route for β-spodumene

Ricardo Ferrari Ferraz[1], Thais M. T. Nascimento[1], Jenifer Tejada Cardoso[1], Raquel A. P. Oliveira[1]

[1]UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO (*Ciência dos Materiais*)

e-mail: ricardo.univasf@gmail.com

β-spodumene (or β-LiAlSi2O6) is a ceramic of great interest due to its optical properties, and has been evaluated for ionizing radiation dosimetry. The proteic sol-gel method has some advantages for the synthesis of this material, such as low synthesis temperatures, high homogeneity and low cost. Whey protein is a promising ligand for the method, as it is considered eco-friendly. Cheese whey represents an important environmental problem when discarded into water sources, because of the high volumes produced and its high organic matter content. The objective of this research is to evaluate the efficacy of the partially hydrolyzed whey protein as an eco-friendly ligand in the sol-gel method for the synthesis of β-spodumene. Structural characterization by X-ray diffraction (XRD) and morphological characterization by scanning electron microscopy (SEM) were performed. Rietveld refinement of X-ray powder patterns (XRPP’s) and mean crystallites size by Debye-Scherrer’s (D-S) and Williamson-Hall’s (W-H) methods were carried out. The XRPP’s and the Rietveld refinement fit confirmed the formation of the single phase β-spodumene for samples calcined at heat-treatment temperatures of 1000 °C and 1100 °C, compatible with reference ICSD 14235, with tetragonal crystal structure. D-S and W-H analysis concluded that the mean crystallites size tend to increase with the increase of the heat-treatment temperature, decreasing the microstrain, due to crystal coalescence. SEM analysis identified polycrystalline particles of micrometric order, with irregular and angular morphology. This research demonstrates the innovative efficacy of the whey as a ligand in the sol-gel method for β-spodumene synthesis, contributing to the perspective that wastes are progressively replaced by suitable treatments for this application.

e-mail: giovana.wozniak@gmail.com

CaF_2detectors (synthetic and natural forms) exhibit a broad range of linear dose responses to various types and energies of ionizing radiation with thermoluminescent (TL) and optically stimulated luminescence (OSL) techniques. The aim of the present work is to study the radioluminescent (RL) response of CaF_2detector based on greenish Brazilian natural fluorite (CaF_2:N) in diverse wavelengths. We produced CaF_2OSL film composed of CaF_2:N crystals in a semi-organic matrix and then made 6 mm diameter pellets. RL signals were evaluated using x-ray photons of 40kV of LUMI22 spectral TL reader (homemade at University of Sao Paulo). The luminescence emission spectrum was detected with an optic fiber spectrometer (Ocean Optics - model FLAME-S-XR1-ES) based on a CCD detector. The three CaF_2samples were irradiated three times with exposure times to the X-ray beam of 10 up to 60 seconds, the background measure was carried out with the same exposure times used to detect the RL, the measurements obtained were the absolute value of the glow intensity as a function of the detected wavelengths emitted. The dose-response analysis was performed from the mean of the three measurements subtracted from the background and by the integral of the dosimetric peaks. It was verified that the signals obtained in the first two peaks emitted in the UV and violet regions are proportional to the dose, and that the dose response is linear in the range of 7 mGy up to 450 mGy. Therefore, it can be concluded in this preliminary study that CaF_2:N detectors have potential for real-time dosimetric applications.

e-mail: yasmim.freire@aluno.ifsp.edu.br

The application of luminescence materials in the dosimetry field is based on the relation between the energy absorbed by ionizing radiation and the intensity of light emitted when the material is stimulated by light or heat [1]. If the luminescence is stimulated by optical energy, it is called optically stimulated luminescence (OSL). Natural and synthetic luminescent materials can be used as luminescent detectors. Alexandrite ($BeAl_2O_4$: Cr^{3+}) is a mineral with potential for OSL detector because its chemical structure is based on the combination of BeO and Al_2O_3, both commercially used as OSL dosimeters [2]. In this study, powdered alexandrite mixed with a polymeric matrix, in the form of pellets, were investigated for OSL dosimetry. The pellets were produced with 10 wt% of alexandrite powder (>75 μm) and 90 wt% of SIQMOL binder. The samples were irradiated with X-Rays using a Moxtek 50 kV cabled source. The OSL measurements were carried out using a Risø reader (model DA-20) with blue light emitting diodes (470 nm, FWHM = 20 nm) delivering 90 mW/cm^{2}at the sample in constant wave mode. R Studio software was used to perform the deconvolutions of OSL curves. Dose-response (0.035 - 0.284 Gy), repeatability and reproducibility were carried out to investigate the samples. The results demonstrate that alexandrite has a linear signal in function of exposition under X-Rays, with a correlation coefficient of R^2= 0.96, and the deconvolution of OSL curve presented three components: fast, medium, and slow. Repeatability test had a variation coefficient of ~ 4.6% (9 runs) and reproducibility of ~ 27.6% (9 samples) was obtained.

Charge-up and metallization effects in LiF crystalsduring sequential ToF-MeV-SIMS with continuous primary ion beams

Beatriz Nattrodt D'Avila[1], Igor Alencar Vellame[1]

[1]Universidade Federal de Santa Catarina (*Física*)

e-mail: beatriznattrodt@gmail.com

Ionic crystals do not amorphize when exposed to ionizing radiation. However, when a large amount of energy is deposited in the target (beyond its linear response), partial radiolysis may occur and its surface becomes metallized. For instance, irradiation of lithium fluoride (LiF) crystals with a beam of energetic ions (MeV range) causes fluorine diffusion, which may lead to fluorine bonding and formation of a gas bubble that could escape from the crystal surface. Meanwhile, due to the similarity to the cation substructure, lithium forms a metallic region. This metallization is a cumulative effect of radiation as a function of the total fluence of particles [1]. The initial motivation for this study was to investigate the metallization process of LiF crystals using Time-of-Flight Secondary Ion Mass Spectrometry with continuous, energetic primary ions (ToF-MeV-SIMS), yet another phenomenon was noted when performing the data analysis. An additional electric field, related to surface charging-up, was observed when bombarding the crystals with 6 MeV copper ions at a charge state of 5+. This field shortened the ToF of secondary ions ejected from the target to the detector. In this work, we determine this additional field and calculates the charge density at the surface, which is in accordance to the accumulation of charge from the primary ions, for the positive secondary ions of lithium and lithium oxide. As similar irradiation conditions are often employed for ion implantation, our findings shed light on reported flux-dependent observations [2].

e-mail: camila.duraes@unesp.br

Apatite can be characterized by observing the tiny etch tracks that become visible when it is placed in a dilute nitric acid solution at room temperature for about 20 seconds [1]. These tracks are produced cumulatively over the geological history of the mineral and their retention age can be determined through half-life data, the amount of ^{238}U, and the number of decays that have occurred [2]. This study aims to characterize apatite grains collected from three plutonic rocks in the northern part of the Borborema Province, Natal, RN, Brazil. Crystallographic characterization is performed using the Fission Track Method (FTM), micro-Raman spectroscopy, and scanning electron microscopy with energy dispersive spectroscopy (SEM/EDS). Isotopic characterization is done through the FTM using a Laser Ablation system coupled to a mass spectrometer (LA-ICPMS). Studying the physical-chemical phenomena that occur during the natural crystallization of apatite, a new protocol for its crystallographic characterization prior to determining its FT age can be developed. The Borborema Province is a region of great structural complexity in northeastern Brazil with several proposed models for its geological evolution [3]. Thus, with this work, the thermal history can be calculated based on the results, and a standard sample from Brazil can be determined to calculate the age of samples collected from other regions of geological interest.

CRYSTALLOGRAPHIC AND ISOTOPIC CHARACTERIZATION OF THE ZIRCON MINERALPEIXE, TOCANTINS, BRAZIL, TO USE AS AGE STANDARD FOR THE FISSION TRACK METHOD

Pedro Brandão Christante[1], Carlos Alberto Tello Saenz[1], Murilo Candido de Azevedo[1]

[1]Universidade Estadual Paulista (*Física*)

e-mail: p.christante@unesp.br

Zircon is a common accessory mineral in igneous, metamorphic and sedimentary rocks, which is able to incorporate trace elements of 5 to 4000 ppm U and 2 to 2000 ppm Th [1]. This makes it widely used in dating processes. This work aims to characterize and date zircon megacrysts from Peixe Alkaline Complex, Brazil, via Raman spectroscopy, optical microscopy, scanning electron microscopy, mass spectrometry LA-ICP-MS and Fission Track Method (FTM), in order to classify this zircon sample and determine whether it can be used as an age standard for the FTM, as a Brazilian sample. The studied zircon mineral from Peixe are megacrystals with dimensions in the order of centimeters that occur in the nepheline syenites of the complex [2]. Because of that, we will cut it into its different faces in order to observe whether the track density has anisotropic behavior. We will do the same by reducing part of the megacrystal into grains (length around 200 µm) with random crystallographic orientations. By using FTM with LA-ICP-MS, it will be possible to obtain simultaneously the fission track age and the isotopic characterization of this sample, that could serve as a standard. It is believed that the zircon megacrystals from Peixe Alkaline Complex nepheline syenites crystallized at 1503±3 Ma, and suffered a metamorphic-metasomatic event that led to Pb loss at about 577 Ma [2].

Investigations of BaZrO3 Perovskite compounds suggest that the band-gap and its trappings are largely responsible for luminescence emissions, and their shape can be controlled by the conditions of synthesis of nanocrystals by the Microwave-Assisted Hydrothermal Method (MAH) [1-2]. Crystals doped with lanthanides have received considerable attention due to the allowed 5d-4f transition, such as trivalent cerium (Ce3+) with good light yield and energy resolution achieved in many materials, having intrinsic phenomena such as luminescence or fluorescence by conversion energy [3]. This work aims to investigate the properties of BaZrO3 Perovskite polycrystals doped with Cerium (Ce) Lanthanides grown by the MAH method. BaZrO3 samples were synthed by the MAH method and characterized using XRD and SEM. XRD results indicated the majority crystalline phase of BaZrO3 with a cubic lattice. SEM images show the present shape and regular from undoped samples. BaZrO3 samples will be synthed and doped with Ce, with the purpose of allowing the identification of changes in electronic structures, their influence on the synthesis process, establishing correlations with their optical properties and investigating energy conversion processes compared to pure BaZrO3, to be analyzed by means of photoluminescence, fluorescence, X-ray absorption and decay measurements.

e-mail: julia.carina@unifesp.br

Kyanite (Al_2SiO_5) belongs to the aluminum silicate class of materials, with their composition mainly attributed to the Al_2O_3 and SiO_2 structural units [1,2]. The mineral's color varies due to impurities, such as Cr, Ti, V, Mn, and Fe. Kyanite is widely used in developing ceramics materials due to its excellent thermal properties and has been investigated as an ionizing radiation detector. This work investigates the optical, structural, and magnetic properties of blue and green kyanite samples from Minas Gerais, submitted to thermal treatment at 300, 500, 700, 900, and 1100°C. The x-ray diffractograms confirmed the triclinic crystalline structure of the studied samples. The energy dispersive spectroscopy (EDS) results show that the samples mainly comprise silicon, oxygen, aluminum, and iron. X-ray fluorescence data reveal the presence of some impurities, including Iron (Fe), Vanadium(V), Titanium (Ti), Chromium (Cr), and Manganese (Mn). The absorption peaks observed forthe samples can be attributed to the substitution of Al^{3+} by Fe^{3+} ions and the Ti^{4+}-Fe^{2+}charge transfer. The magnetic behavior of the as-prepared samples and those submitted to athermal treatment of 1100 ºC was investigated at 2 K and 300 K temperatures. Electronparamagnetic resonance (EPR) spectra revealed the presence of iron ions in the crystallinestructure of the green and blue kyanite samples, with larger spectral line widths for thegreen kyanite, indicating a higher iron content than for the blue sample. X-ray fluorescencestudies also showed higher iron contents in green kyanite than in the blue sample, confirming the EPR results.

Fission-tracks dating in apatite: provenance studies by LA-ICP-MS

Jaqueline Dickel Bilhar[1], Carlos Alberto Tello Sáenz[2], Maria Lidia Medeiros Vignol-Lelarge[3], Cleber Jose Soares[4]

[1]Universidade Estadual Paulista (*Posmat*) , [2]Universidade Estadual Paulista (*Física*) , [3]Universidade Federal do Rio Grande do Sul, [4]ChronusCamp Research Thermochronology Laboratory

e-mail: j.bilhar@unesp.br

Apatite is a phosphate mineral, rich in uranium and present in various types of igneous, metamorphic and sedimentary rocks. This mineral is the most used by Fission-Tracks dating (FT), allowing the reconstruction of thermal events that occurred in the first kilometers of the upper crust, in addition to its use in sedimentary provenance studies. FT dating is based on the quantitative relationship between the density of parent and daughter isotopes and their decay constant. To estimate the number of daughter atoms, the FT dating method is based on the accumulation of defects generated by the spontaneous fission of 238U in the mineral´s crystalline structure. The closing temperature for apatite is around 120 °C, from which the record of FT formation is preserved [1]. The amount of parent atoms (238U), can be discovered using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS). This technique estimates the amount of 238U of grain directly and quickly [2]. The methodological procedures used in this work consist of choosing the apatites, mounting grains in epoxy resin, polishing, and subsequent etching with nitric acid to reveal the FT. Subsequently, for each grain, the surface FT are counted in an optical microscope and is measured confined FT and etch pit, used as a kinetic parameter (Dpar) to realize the thermal modelling of the sample. The next step is to mensure 238U directly in the mineral, using LA-ICP-MS. The different ages of fission tracks obtained in studies of sedimentary provenance allow differentiating the sources of sediments.

INVERTED MODEL OF ANNEALING VIA AGES OF FISSION TRACKS BY LA-ICP-MS OF APATHITE SAMPLES COLLECTED FROM THE PERUVIAN CENTRAL ANDES.

BRUNO HENRIQUE VAZ SANTOS[1], Murilo Candido de Azevedo[1], Carlos Alberto Tello Saenz[1]

[1]Universidade Estadual Paulista (*Física*)

e-mail: bruno.vaz@unesp.br

Under an adequate chemical etching, the tracks left by the nuclear fissions of 238U are enlarged and can be seen under an optical microscope to determine the density of fossil tracks. 238Uppm can be evaluated using the LA-ICP-MS spectrometry technique by relating the average counts per second of the isotopes of 238U and 43Ca with the 238Uppm of a known standard sample. With the density of fossil tracks and the 238Uppm it is possible to calculate the corrected age of the sample based on the shortening of confined tracks produced by the annealing process depending on the temperature and time conditions these samples are subjected in their place of origin. The variety in the lengths of confined tracks can be represented by a length probability density function that characterizes their distribution. Then, from the Monte Carlo method, thermal histories are artificially obtained with a probability density function of confined tracks lengths and apparent ages. These thermal histories can be discarded or appreciated as the observed data and theoretical data converge towards statistical compatibility. Two samples of apatite were submitted to the inverted model to determine their thermal histories with the purpose of proposing a geological model of tectonic dynamism, taking into account what is already known about the region ([1]Chavez et al., 2021; [2]Mamani et al., 2010).

INVESTIGATION OF ALPHA PARTICLE EJECTIONFROM ZIRCON MINERAL

LUANA ROSA BILAC CAETANO[1], Carlos Alberto Tello Saenz[1], Luiz Augusto Stuani Pereira[2]

[1]Universidade Estadual Paulista (*Física*) , [2]Universidade Federal de Campina Grande (*Física*)

e-mail: luana.bilac@unesp.br

Zircon contains traces of unstable actinide elements [1], whose radioactive decay comprises the emission of alpha, beta and gamma radiation particles in the chains (U-Pb and Th-Pb) and the spontaneous fission events of the U-238 isotope. The self-irradiation process, in geological time, damages the zircon crystalline structure by altering the physical and chemical properties of the bulk mineral. Alpha decay is the radioactive event that contributes the most to bulk damage to the mineral lattice and the loss of radiogenic Pb and He, which results in skewing of geological ages.The refore, a quantitative assessment of alpha emanation from the zircon surface was performedusing a CR-39 as an external alpha detector. A CR-39 detector in 2π geometry exposed to a zircongrain for 60 hours at a temperature of 40° degrees resulted in an average alpha-track density of 10^4 tracks/cm 2 . Moreover, an investigation of the alpha emanation from different zircon grains from standard samples (FCT and KGD) indicates the inhomogeneity of U and Th concentrations in the minerals, which may disperse the measured U-Th/He ages. The heterogeneous emanation of particles can be attributed to imperfections in the crystalline structure that may be inherent to the crystallization of zircon or acquired during its geological history [2]. Understanding the alpha emission of zircon in relation to its crystalline structure is fundamental for the U-Pb and (U-Th)/He methods.

Photodetection in bismuth chalcohalides pellets: purevs composite materials

Maia Mombrú Frutos[1], Heinkel Bentos Pereira[2], Laura Fornaro[2], Ivana Aguiar[3] [1]Facultad de Química- Universidad de la República (*Área Radioquímica, Departamento Estrella Campos*) , [2]Centro Universitario Regional Este, Universidad de la República, [3]Facultad de Química- Universidad de la República

e-mail: maiamombru@gmail.com

Bismuth based semiconductor materials are increasing in popularity due to their potential in optoelectronic applications such as solar cells and radiation detection. In particular, BiSI has been studied for these purposes, especially in film deposition. In this work, we presentthe study of photodetection in BiSI pellets. BiSI nanorods were synthed by either a solutionor solvothermal method, both developed in our group [1]. The solution method yielded pure crystalline BiSI nanorods in the Pnma crystal group, while the solvothermal method produced a composite of BiSI nanorods and amorphous carbon particles. The pellets were constructed by cold pressing in a uniaxial press, followed by a heat treatment for 3.5 hours at 250ºC under Ar atmosphere. Two pellet thicknesses were tested: 1.5 and 2.5 mm, while the diameter was kept at 10 mm. Pellets made with the pure product showed proved to be more brittle than pellets with the composite. Prototype devices were built by depositing Au contacts through evaporation and Pd wires were attached with Aquadag and encapsulated with acrylic.

I-V curves were measured both in the dark and under UV light. Measurements were carried out up to 600 V and the current measured with a picoammeter. The resistivity was increased four orders of magnitude from $10^8$to $10^{12}$when changing from the pure material to the composite, respectively. This is in accordance to the fact that the composite has amorphous structure that limits the conductivity. However, the response to UV light was similar in both cases, ranging from 0.5-0.6. This work is a first approximation of a simple photodetection device with an easy to synthe novel material.

e-mail: djanes@estudante.ufscar.br

Scintillators play a central role in modern engineering as converters of high-energy ionizing radiation (such as X-rays) into visible light, being one of the main components of radiation detectors. To meet the high demand for these components, in combination with the development of new materials and techniques for the production of increasingly efficient scintillators, a series of research has been carried out in recent decades. Yttrium Aluminum Garnet (YAG) is a material that stands out in different fields of scintillation. To produce transparent ceramics scintillators, in this work, Ce-doped YAG nanoparticles were prepared by the co-precipitation method, followed by calcination at 1100 °C. To achieve the desired microstructure and transparency for the final application of the material, conformation, and sintering were tailored to achieve the best parameters for obtaining such properties. Seeking to achieve a high green density through a colloidal process, using the pressure slip casting method, the concentration of solids in the colloidal suspension was a key parameter, as well as the colloidal stability and pressure applied during the slip casting. The final densities obtained for the different parameters were measured and compared. In this way, the purpose of this work is to present a methodology for the production of transparent ceramics scintillator by pressure slip casting method, seeking to reach the final properties necessary for use in the Sirius fourth generation Synchrotron, located at the National Center for Research in Energy and Materials (CNPEM) in Brazil.

Radiation Damage in Zircon Grains: A NewClassification Based on Optical Analysis

Murilo Candido de Azevedo[1], Carlos Alberto Tello Sáenz[1], BRUNO HENRIQUE VAZ SANTOS[1], Luiz Augusto Stuani Pereira[2]

[1]Universidade Estadual Paulista (*Física*) , [2]Universidade Federal de Campina Grande (*Física*)

e-mail: murilo.azevedo@unesp.br

Zircon is a widely-used accessory mineral that is valuable in the study of geothermal and chronological events, providing insights into the geological history of the Earth. Due to its crystallographic properties, this mineral has the ability to accumulate heavy chemical elements, such as uranium in its crystal lattice at concentrations in parts per million (ppm) [1]. Zircon is also capable of detecting self-radiation, making it a useful tool in this field of study. The 238U isotope spontaneously fissions, leading to the release of high energy and the creation of a disturbance in the crystal structure of nanometric dimensions known as fission track. This phenomenon provides valuable structural information about zircon and can also be used to date the mineral using the fission-track method (FTM) and U-Pb chronometry [2]. After etching, tracks can be observed on zircon surface under an optical microscope. The appearance of these tracks can vary depending on the structural characteristics of the grain. Some layers may not reveal fission tracks or may be destroyed, while others may remain intact or display different patterns of track density. These variations allow the mineral to be classified into different categories [3], with distinct patterns observed depending on the properties of the parent rock, such as whether it is from a new or older region, granitic, or from a basin. Based on the optical analysis of over 1000 zircon grains from various samples, a new classification of zircon grains is proposed.

Radioluminescence of Ce^{3+} doped $CaAl_2O_4$ as a function of annealing temperature

Walace Rodrigues da Silva Júnior[1], Carina Ulsen[2], Neilo Marcos Trindade[3]

[1]Universidade Estadual Paulista (*Pós-Graduação em Ciência e Tecnologia de Materiais*) ,
[2]University of São Paulo, [3]Instituto de Física da Universidade de São Paulo (*Física Nuclear*)

e-mail: walace.junior@unesp.br

Recent studies show that Ce^{3+} can be a good candidate in the $CaAl_2O_4$ matrix for scintillation purpose. The scintillators are luminescent materials that absorb ionizing radiation and convert it into light within the region of the visible/IR. These devices have applications such as dosimetry, nuclear medicine and high energy physics. To measure the scintillation properties, radioluminescence (RL) is a powerful technique used since RL is a prompt luminescence emitted by a material under ionizing radiation exposure [1]. In this work, undoped and cerium-doped ($CaAl_2O_4$:Ce^{3+}) powders were synthesized by combustion synthesis in solution. Aluminum nitrate, calcium nitrate, and urea are used as starting materials. Urea acts as a fuel for combustion and cerium nitrate provides the doping ions. The mixture of reagents was kept in a conventional furnace at 500ºC for about 5 min. After combustion, the crystalline powder was crushed in a porcelain crucible. The samples were annealed for 2h at five different temperatures (600, 700, 800, 900, and 1000°C); and the effects of ionizing radiation were investigated using the RL technique. To irradiate the samples, we used a custom-made equipment named LUMI22, that consists of an X-ray tube (Moxtek 50kV, 0.2mA), a spectrometer (Ocean Optics, FLAME-S-XR1-ES, range 200-1050nm) coupled with a fiber optic (QP1000- 2-UV-VIS). Preliminary results of the undoped sample showed a broad RL peak at ~520 nm which can be caused by intrinsic defects, e.g., oxygen vacancies. Doped samples showed a peak at 400 nm which may be caused by 5d-4f transition in the crystalline structure. So far, it can be concluded from this preliminary study that $CaAl_2O_4$:Ce^{3+} detectors have potential for applications as scintillators.

Response of CsI:Pb scintillator crystal to neutron radiation

Maria da Conceição Costa Pereira[1], Tufic Madi Filho[2], José Roberto Berretta[2], João Paulo da Silva Alves[2]

[1]Instituto de Pesquisas Energéticas e Nucleares (*Centro de Tecnologia das Radiações - CETER*)
, [2]Instituto de Pesquisas Energéticas e Nucleares

e-mail: macoper@ipen.br

The helium-3 world crisis requires a development of new methods of neutron detection to replace commonly used ^{3}He proportional counters. In the past decades, great effort was made to developed efficient and fast scintillators to detect radiation.[1] These detectors should, then, be carefully characterized both experimentally and by means of advanced simulation code. Ideally, the detector should have the capability to separate neutron and gamma induced events either by amplitude or through pulse shape differences. As neutron sources also generate gamma radiation, which can interfere with the measurement, it is necessary that the detector be able to discriminate the presence of such radiation. Considerable progress has been achieved to develop new inorganic scintillators, in particular increasing the light output and decreasing the decay time by optimized doping.

Crystals may be found to suit neutron detection. In this report, we will present the results of the study of lead doped cesium iodide crystals (CsI:Pb) grown in our laboratory, using the vertical Bridgman technique. The concentration of the lead doping element (Pb) was studied in the range $5x10^{-4}$M to 10^{-2}M. The crystals grown were subjected to annealing (heat treatment). In this procedure, vacuum of 10^{-6} mbar and continuous temperature of 350°C, for 24 hours, were employed. In response to neutron radiation, an AmBe source with energy range of 1 MeV to 12 MeV was used. The activity of the AmBe source was 1Ci Am. The fluency was 2.6×10^6 neutrons/second. The operating voltage of the photomultiplier tube was 1300 V; the accumulation time in the counting process was 600 s and 1800 s. The scintillator crystals used were cut with dimensions of 20 mm diameter and 10 mm height. The Monte Carlo method was used to determine the neutron flux arriving in the detector and the calculated values were obtained by means of MCNP code.

Study of optically stimulated luminescence propertiesof amazonite

Roberto Turibio Ebina Kawanaka Martins[1,2], Carina Ulsen[3], Elisabeth Mateus Yoshimura[2], Neilo Marcos Trindade[2]

[1]Instituto Federal de Educação, Ciência e Tecnologia de São Paulo (*Departamento de Física*) , [2]Instituto de Física/USP (*Departamento de Física*) , [3]Universidade de São Paulo (*Engenharia de Minas e Petróleo*)

e-mail: r.turibio@aluno.ifsp.edu.br

In the group of K-rich Feldspars, amazonite is a variety that attracts attention due to its blue-greenish color. Recently, efforts have been made to understand and apply the luminescence properties of this mineral [1]. In view of that, the aim of this work was to study the Optically Stimulated Luminescence (OSL) of amazonite, a microcline feldspar variety (KAlSi3O8). OSL characteristics, such as dose-response, repeatability and reproducibility, and fading were analyzed in a TL/OSL commercial reader Risø DA-20. The samples were irradiated with a beta source 90Sr/90Y, delivering a dose rate of 10 mGy/s. Also, chemical and structural characterization have been done from X-Ray Fluorescence (XRF) and X-Ray Diffraction (XRD), respectively. The amazonite showed the presence of some impurities, such as PbO, one of the agents in the coloration of amazonite; and, from XRD data, it was possible to observe an albite phase. The CW-OSL curves showed a high intensity with a fast decay for the dose range studied (0.01 - 0.3 Gy), and from the coefficient of linearity g(D), it was possible to conclude the dose-response showed a linear behavior for the range studied. For reproducibility and repeatability, a coefficient of variation (C.V.) of 3.7% (12 samples) and 0.4% (12 runs), respectively, was obtained. OSL fading at room temperature was ~23% within one hour after irradiation.

Thermoluminescence, Fluorescence and Electron Paramagnetic Resonance of natural alexandrite.

Alexia Oliveira Silva[1,2], Matheus Cavalcanti dos Santos Nunes[3,2], Elisabeth Mateus Yoshimura[2], Orlando Rodrigues Junior[4], Neilo Marcos Trindade[2]

[1]Instituto Federal de Educação, Ciência e Tecnologia de São Paulo (*Física*) , [2]Instituto de Física da Universidade de São Paulo (*Física Nuclear*) , [3]Universidade Estadual Paulista (*Pós-graduação em Ciências e Tecnologia de Materiais*) , [4]Instituto de Pesquisas Energéticas e Nucleares

e-mail: alexia.o@aluno.ifsp.edu.br

Recent studies have proposed the investigation of alexandrite mineral ($BeAl_2O_4:Cr^{3+}$) as a potential luminescent dosimeter. Despite this, in-depth studies of defects and luminescent centers in alexandrite were not investigated. It is proposed to characterize the thermoluminescence (TL) emission spectra, fluorescence (FL) and electron paramagnetic resonance (EPR) of alexandrite. TL dosimeters, when stimulated by thermal energy, emit light proportional to the dose of ionizing radiation previously absorbed. The emitted wavelength can be measured through thermoluminescence emission spectra. On the other hand, EPR and FL provides additional information about mineral structure, enabling the study of the effects of ionizing radiation on the sample. For TL, the samples were irradiatedwith X-rays and measured by Lumi22 homemade system. EPR measurements were carriedout using a Bruker EMXplus spectrometer operating in the X-band at room temperature, 2mW microwave power, 100 kHz modulation frequency and 0.25 mT modulation amplitude. The FL spectra were measured using the Duetta spectrofluorometer, with a 75 W xenon arclamp included. The data was collected by scanning excitation wavelengths in 360-480 nmand recording emission in the wavelength range of 670-740 nm. Preliminary results indicatethat the TL emission spectra presented two peaks, at ~80°C and ~175°C, with emissioncentered between 600 nm - 700 nm, related to Fe^{3+} and Cr^{3+}, also detected by EPR. TheFL spectra showed two signals: an emission centered at 680 nm (Cr^{3+} in inversion center),and at 700 nm (Cr^{3+} in mirror symmetry). The results of all techniques used in this worksuggest that emissions are correlated to Cr^{3+} and Fe^{3+} ions.

Recently, spintronics has emerged as a candidate to supplant conventional silicon-based electronics. A notable milestone in spintronics was achieved by Dyakonov and Perel, who identified the transverse accumulation of spin in correlation to a charge current[1], called the Spin Hall Effect. Also, it is essential to consider that these moments can originate fromeither the spin moment or orbital moment through the orbital Hall effect (OHE). In addition,this accumulation of spins can also be related to other effects, such as the Valley Hall effect(VHE) and the Rashba-Edelstein effect (REE). High-order topological materials known as transition metal dichalcogenides (TMDs), particularly the semiconductor MoS2, have gained significant interest among the materials that exhibit these distinct effects. This material predicts OHE, VHE, and REE for states near the Fermi energy. The existence of SHE is only expected for the conducting states of this material. Therefore, it is possible to induce the SHE through the electronic population of these conducting states. This population of the conducting states can be obtained by multiple approaches, such as by exciting the valence band electrons with light or by the presence of conductive edge states in specific symmetries of this material [2,3]. Spin pumping is an experiment that investigates specific effects. It injects angular momentum dynamically from a nearby ferromagnetic layer. A magnetic insulator like YIG can reduce the impact of specific effects and create a pure spin current. We focused on evaluating the contributions of different effects that generate magnetic moment accumulations transverse to the charge currents, specifically looking at the induced spin Hall effect.[1] D’ Yakonov Perel J. Emergent phenomena from topology in tellurium

Jaime F de Oliveira[1], Magda Bittencourt Fontes[1], Elisa Baggio Saitovitch[1], Marcello Barbosa da Silva Neto[2], Carsten Enderlein[3]

[1]Centro Brasileiro de Pesquisas Físicas (*COMAN*) , [2]Universidade Federal do Rio de Janeiro (*Departamento de Física*) , [3]Universidade Federal do Rio de Janeiro (*Instituto de Fisica*)

e-mail: jaimefdeoliveira@gmail.com

Elemental tellurium crystalizes in covalently bound atomic helices, arranged in a hexagonal lattice in which the helices are connected via the van-der-Waals interaction. It is a semiconductor with a 330 meV band gap and a strong spin-orbit interaction which leads to a unique spin texture of the valence band. Along the helical screw direction, the spin texture allows parallel or antiparallel current-induced magnetization and implies a recently identified spin Hedgehog, when samples are sufficiently p-doped [1]. We present an experimental AC-magneto transport study for different frequencies of Sb-doped and chemically pure needle-shaped tellurium single crystals. The current flows along the chiral screw axis, while the direction of the external magnetic field is perpendicular and longitudinal in relation to the chiral screw axis. The behavior of resistance as a function of frequency is consistent with topological effects which includes the emergence of a strong pseudomagnetic field.

Machine learning for materials discovery: Two-dimensional topological insulators

Gabriel Ravanhani Schleder[1], Bruno Focassio[2], Adalberto Fazzio[3]

[1]Brazilian Nanotechnology National Laboratory, [2]Brazilian Center for Research in Energy and Materials, [3]Brazilian Center for Research in Energy and Materials (*Ilum Escola de Ciência*)

e-mail: gabriel.schleder@lnnano.cnpem.br

One of the main goals and challenges of materials discovery is to find the best candidates for each interest property or application. Machine learning rises in this context to efficiently optimize this search, exploring the immense materials space, consisting of simultaneously the atomic, compositional, and structural spaces. Topological insulators, presenting symmetry-protected metallic edge states, are a promising class of materials for different applications. However, further development is limited by the scarcity of viable candidates. Here we present and discuss machine learning-accelerated strategies for searching the materials space for two-dimensional topological materials. We show the importance of detailed investigations of each machine learning component, leading to different results. Using recently created databases containing thousands of ab initio calculations of 2D materials, we train machine learning models capable of determining the electronic topology of materials, with an accuracy of over 90%. We can then generate and screen thousands of novel materials, efficiently predicting their topological character without the need for a priori structural knowledge. We discover 56 non-trivial materials, of which 17 are novel insulating candidates for further investigation, for which we corroborate their topological properties with density functional theory calculations. This strategy is 10× more efficient than the trial-and-error approach while a few orders of magnitude faster and is a proof ofconcept for guiding improved materials discovery search strategies.

e-mail: thaiscpeixoto@yahoo.com.br

The electronic topology of Bi_4Te_3, composed of alternating $Bi_2$and Bi_2Te_3layers, was investigated by density functional theory and by angle-resolved photoemission spectroscopy (ARPES). We find, remarkably, that there are three adjacent strong topological gaps with associated protected surface states within a 2-eV range of the Fermi level. Additionally, a surface-state Fermi surface with strong hexagonal warping is observed. The spin texture of topological states in Bi_2Se_3around the Fermi level shows a linear dispersion with all spins states parallel to the surface with no warping shaped Fermi surfce[1], unlike, the $Bi_2Te_3$and Bi_4Te_3that show a hexagonal warping[2] of the electronic states in the vicinity of the Fermi level. In the Fermi surface with this sort of warping the spin texture has a component out of plane of the surface[3]. As in $Bi_4Te_3$the warping was found to be much stronger then in Bi_2Te_3, it shell have a larger out of plane spin component which impplies in a high potential applications in spintronics. In this presentation I will show the experimental results for $Bi_4Te_3$and I will also discuss how the combination of ARPES technique and synchrotron radiation helped to solve this system.

The “ABC” of adatomic collapse in correlated Moiréless multi-graphene

Antonio C. Seridonio[1]

[1]Universidade Estadual Paulista (*Physics and Chemistry*)

e-mail: antonio.seridonio@unesp.br

In this talk, we discuss the multi-graphene of ABC-type stacking, namely, the 2D version of the 3D multi-Weyl semimetals with the topological charge Fano effect[1], and its possibility of having virtual bound states, in particular, residing within the Coulomb insulating gap of an Anderson-like adatom[2]. Wondrously, one of the virtual states constitutes the counterpart of the atomic collapse phenomenon proposed in relativistic atomic Physics, while the second emerges as its particle-hole symmetric, analogous to a positron state. Thus, the effect is introduced as the adatomic collapse, which occurs due to a flat band with a dispersionless state and a divergent density of states $\sim|\varepsilon-\varepsilon_F|^{2/J-1}$ for $J\geq3$ near the Fermi energy ε_F, where $J\pi$ is the Berry phase. We verify this scenario based on the Kramers-Kronig transformation of the quasiparticle broadening, from where we observe that the aforementioned van Hove singularity induces virtual bound states. Counterintuitively, near the singularity, we reveal these states above and below the Fermi energy correlated to the existence of the bottom and top edges of the Coulomb insulating region, respectively. As such a behavior rises without a twist, the system is known as Moiréless and the phenomenon emerges also assisted by the adatom Coulomb correlations. Therefore, the current findings make explicit that the ABC multi-graphenen system is a rich environment for strongly correlated phenomena and emulation of relativistic Physics.

Unveiling quantum phase transition by disorder and defects in 2D-materials: Jacutingaite Family

Adalberto Fazzio[1], Felipe Crasto de Lima[2], Roberto Hiroki Miwa[3]

[1]Brazilian Center for Research in Energy and Materials (*Ilum Escola de Ciência*) , [2]Brazilian Center for Research in Energy and Materials (*Ilum*) , [3]Universidade Federal de Uberlândia (*Instituto de Física*)

e-mail: adalberto.fazzio@ilum.cnpem.br

Transition metal dichalcogenides have been the subject of numerous studies addressing technological applications and fundamental issues. Within this class of materials, a single-layer PtSe2 is a semiconductor with a trivial bandgap. In contrast, its counterpart with 25% of Se atoms substituted by Hg, Pt2HgSe3 (jacutingaite, a naturally occurring mineral), is a 2D topological insulator with a large bandgap. We investigate the energetic stability and the topological transition in Pt(HgxSe1-x)2 as a function of alloy concentration and the distribution of Hg atoms embedded within the PtSe2 host. Our findings reveal the dependence of the topological phase on the alloy concentration and robustness regarding the distribution of Hg in ordered or random configurations. We also show that vacancies randomly distributed induce a quantum transition trivial to topological in doped transition metal dichalcogenides. Finally, we discuss a fundamental issue, whether a topological insulator protected by time-reversal is robust enough under a transformation to an amorphous state. The crucial role of translational symmetries in building the theory of topological insulators raises the question: to what extent is translational symmetry necessary for a topological state to retain its properties?

Compositional and cycling effects in several high entropy alloys foreseen for solid-state hydrogen storage

Claudia Zlotea[1], Nayely Pineda-Romero[1], Anis Bouzidi[1], Renato Belli Strozi[1], Guilherme Zepon[2], Walter José Botta Filho[3]

[1]Centre national de la recherche scientifique (*ICMPE*) , [2]Univerdade Federal de São Carlos (*DEMa*) , [3]Univerdade Federal de São Carlos

e-mail: claudia.zlotea@cnrs.fr

Among various materials for solid-state hydrogen storage, alloys and intermetallics forming hydrides are one of the most important classes due to their high-volume density, reversibility, and safety. Recently, the metallurgy paradigm of high entropy alloys (HEAs), initially intended to enhance the mechanical properties [1], has been proposed for hydrogen storage [2]. The principle is laid on the mixing of elements close to the equimolar proportion for systems up to five and more elements. This may lead to the formation of simple single-phased solid solutions (bcc, fcc and hcp) with interesting properties for solid-sate hydrogen storage. We will focus here on the physicochemical and the hydrogen absorption/desorption properties of several series of HEAs (containing mainly refractory, transition and light metals) and the insights that can be obtained from experiments at large-scale facilities, mainly neutron and X-ray diffraction [3-5]. The role of chemical composition will be highlighted as function of the local lattice distortion and electronic properties [3-5]. For example, in situ neutron diffraction at D1B ILL has clearly evidenced a drastic decrease of the desorption temperature associated with the phase transition from a fcc hydride to a bcc alloy in the Al-containing materials [6]. Moreover, the absorption/desorption cycling effects on these materials will be clarified by the help of advanced characterisation techniques such as, pair distribution function analysis of total X-ray scattering and positron annihilation spectroscopy. This approach is envisioned to clarify the role of the chemical composition and the cycling effect on the hydrogen storage performances of HEAs.

Corrosion behavior of high entropy alloys

ROCHE Virginie[1]

[1]GRENOBLE INP SA LEPMI (*LEPMI*)

e-mail: virginie.roche@grenoble-inp.fr

In this study, the effects of three different nickel concentrations on the microstructure, hardness, and corrosion properties of AlCrFeCoNix (x = 1.0, 1.5, 2.0) high entropy alloys (HEA) were investigated.

The alloys were obtained by arc melting from high-purity raw materials and subjected to heat treatment at 1125 ◦C for 5 h. Microstructural characterization revealed a dendritic morphology for the equimolar and AlCrFeCoNi1.5 alloys, while the AlCrFeCoNi2 alloy presented a hypoeutectic microstructure. Differences in microstructure and chemical composition were observed between the dendritic and interdendritic regions, with clear segregation of Cr in the interdendritic areas. The increase in Ni content and the heat treatment resulted in the formation of the FCC phase, consequently reducing the alloys' hardness.

The corrosion properties of HEA were evaluated by potentiodynamic polarization and electrochemical impedance spectroscopy methods in a 3.5% NaCl solution. A passive film was formed at the corrosion potential for the three compositions, that resulted in high resistance to localized corrosion mainly after heat treatment as indicated by higher pitting potential and larger passive plateau. EIS results indicate that the protective film's formation depends on Ni content, which is also related to the FCC/BCC ratio and phase compositions. The heat treatment resulted in a more homogeneous and thicker oxide film, as indicated by the reduction of Q and Ceff of the alloys in this condition. The protective film's formation depends on Ni content, which is also related to FCC/BCC ratio and phase compositions.

Design, Processing and Hydrogen Storage Properties of Multicomponent Alloys Derived from the TiZrNbCrFeNi System

Ricardo Floriano[1], Gaspar Andrade[2], Gabriel L. B. G. Fontana[1], Igor S. Vicente[1], Guilherme Zepon[3,4]

[1]Universidade Estadual de Campinas (*Faculdade de Ciências Aplicadas*) , [2]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*) , [3]Univerdade Federal de SãoCarlos (*DEMa*) , [4]Universidade Federal de São Carlos

e-mail: rflorian@unicamp.br

Multicomponent alloys have been considered as a new class of metal hydrides. The extensive compositional field that can be explored opens new horizons to find novel metal hydrides with tunable hydrogen storage properties [1,2]. In this study, two multicomponent alloys with a single C14 laves phase and a VEC of 6.4 were designed by thermodynamic calculations from the TiZrNbCrFeNi system with different A/B ratios, such as (TiZrNb)60(CrFeNi)40 and (TiZrNb)40(CrFeNi)60. Our aim was to investigate the influence of A and B elements (A: elements forming hydride, B: elements with low chemical affinity with hydrogen) of the TiZrNbCrFeNi system on the hydrogen storage capacity, activation, absorption, and desorption kinetics. We prepared the selected alloys by arc melting under an inert atmosphere and analyzed their microstructure using XRD with the Rietveld method, SEM/EDS, and TEM characterization techniques. The hydrogen storage performance was evaluated using absorption/desorption kinetics and PCT isotherms. Our results revealed that the arc-melted equiatomic TiZrNbCrFeNi alloy contained two C14 Laves phases with slight differences in unit cell parameters, while the non-equiatomic alloys had a high amount of C14 laves phase with minor traces of BCC phases with fractions inferior to 13%. The microstructural features demonstrated the existence of compositional gradients in the alloys, which matched very well with the different phases observed and fitted in the XRD analysis. At 473 K, the equiatomic TiZrNbCrFeNi alloy could reversibly absorb and desorb 1.1 wt% of hydrogen with a maximum H/M ratio of 0.75. The fractions of A and B elements in the TiZrNbCrFeNi alloy directly impacted the performance on activation, hydrogen capacity, and kinetics of the alloys studied here.

Developments and Industrializations of Zr-based Bulk Metallic Glasses and Fe-based Glassy and Nanocrystalline Alloys

Akihisa Inoue[1]

[1]Josai International University

e-mail: ainouebmg@yahoo.co.jp

Multicomponent alloys have attracted increasing interest for the last three decades since the first synthesis of multicomponent bulk metallic glasses (BMGs) in 1990. The multicomponent alloys reported to date are classified to BMGs, BMG composites, high entropy (HE) BMGs, HE crystalline alloys and marginable BMGs. When we focus on engineering application, the most widely commercialized alloys are BMGs. Their BMGs are roughly classified to nonmagnetic Zr-based and ferromagnetic Fe-based type compositions. The former type is typically composed of Zr-Al-Ni-Cu and Zr-Al-Ni-Cu-(Ti,Nb) systems and the latter type is Fe-Cr-(P,B,C,Si), Fe-(Cr,Nb)-P-B and Fe-(Cr,Nb)-(P,B,Si) systems. The commercialization products have been usually produced by direct die casting from liquid for the Zr-based BMGs, while the Fe-based glass-type alloys have been produced by high-pressure gas atomization and ultrahigh water atomization. The former BMGs have been used as various structural materials such as casing, housing, pin spring, hinge, ratch cover writing tool, precise gears, knife, optical mirror, sporting goods and ornaments etc., while the latter glass-type alloys exhibit unique soft magnetic properties with the features of low coercive force (Hc), good high-frequency permeability, low core loss and high electrical resistivity in combination with high glass-forming ability which can be prepared as spherical powders over the whole particle range by high-pressure gas or ultrahigh-pressure water atomization and the powder-consolidated cores have been used as high performance inductors with low core losses even in a high frequency range up to 3 MHz. The low core loss characteristics combined with high-frequency permeability have attracted rapidly increasing engineering importance, because of the applications to advanced articles such as smartphone, notebook PC, DC/DC convertor, point of load power supply, digital camera, automobile AV equipment, car navigation system and RFID sheet etc. New

Effect of Solution Heat Treatment on Microstructure and Properties of Ni-15Nb-M alloys (M = Al, Ti, Cr, Fe)

Conrado Ramos Moreira Afonso[1], Mariana Correa Rossi[1], Vinicius Cardoso Ottani[2], Mariana Santos Pereira[3]

e-mail: conrado@ufscar.br

Ni-based superalloys are widely used in critical components of aircraft engines and turbines and also in the petrochemical industry, for applications in highly corrosive environments [1]. These alloys have as main characteristics their superior mechanical, corrosion and oxidation resistance at high temperatures, as well as creep resistance. The chemical composition associated with carrying out heat treatments directly influences the phases formed (such as the ordered cubic phase γ'-$Ni_3(Al,Ti)$ in the fcc γ-Ni matrix), and depending on the alloying elements and fraction, there is the possibility of an increase in mechanical strength through hardness. There is a certain gap in the literature regarding the study of ternary Ni-Nb-based superalloys [2], and the influence of the third alloying element on the microstructure and properties. In this context, the objective of the study is to characterize pseudo-eutectic alloys of the Ni-15Nb-M system (M = 2 to 15 wt.% for Al, Ti, Fe, Cr) and investigate the influence of alloy elements and solution heat treating (SHT) on their microstructure and properties through X-Ray Diffraction (XRD), Optical Microscopy (OM), Scanning (SEM) and Transmission Electron Microscopy (TEM) and Vickers Microhardness. Thus, the main results are that the addition of Cr significantly affects the hardness and in the Ni-15Nb-Msamples the solution heat treatment showed less significant effect. All Ni-15Nb-M ternaryalloys system (M=Al, Ti, Cr, Fe) pseudo-eutectic alloys showed microhardness and microstructural changes after solution heat treatment. The alloying elements that most contributed to increase the mechanical strength of the as-cast Ni-15Nb alloy were Cr and Al and the Cr addition provided the highest hardness among all compositions. After solution HT, hardness of Ni-15Nb-M was significantly decreased in all samples, mostly in the Ni-15Nb-2Al and Ni-15Nb-15Cr.

Effects of warm-rolling process on CrMnFeCoNi multicomponent alloy

Caroline Nazare Goncalves[1], Moses James Paul[2], Bernd Gludovatz[3], Francisco Gil Coury[4], Eric Marchezini Mazzer[5], Guilherme Zepon[6]

[1]Universidade Federal de Minas Gerais (*Engenharia Metalúrgica, Materiais e de Minas*) , [2]University of New South Wales (*Mechanical and Manufacturing Engineering*) , [3]University of New South Wales (*Mechanical and Manufacturing Engineering*) , [4]Univerdade Federal de São Carlos (*Engenharia de Materiais*) , [5]Federal University of Sao Carlos (*DEMa*) , [6]Federal University of Sao Carlos (*Departamento de Engenharia de Materiais*)

e-mail: carolgoncalves92@hotmail.com

The study aimed to investigate the impact of warm-rolling on the microstructure and mechanical properties of the equiatomic CrMnFeCoNi high entropy alloy (HEA) with a face-centered cubic (FCC) structure. Warm-rolling was performed on the HEA, achieving reductions in thickness of 76% and 90% at a temperature of 773 K. To elucidate the influence of warm-rolling, a comparison was made with cold-rolled HEA samples, both deformed with and without subsequent annealing. Despite undergoing similar deformation as the cold-rolled samples, they exhibited a lamellar microstructure that was notably coarser than the cold-rolled material. This disparity in microstructure could be attributed tothe dynamic annihilation of dislocations during the warm-rolling process. While the cold-rolled material displayed a single-phase FCC structure without any indication of second phases, it is essential to consider the presence of a Cr-rich body-centered cubic (BCC) phasereported in the literature during annealing at 773 K. Consequently, the possibility of a Cr-rich BCC phase should not be disregarded. Nano-twins were introduced during both warmand cold-rolling processes and were retained in the cold-rolled sample even after annealingat 773 K for 1 hour. Chemical fluctuations observed in the warm-rolled HEA indicated theformation of second phases, which was not observed in the similarly cold-rolled samples. Thus, warm and cold-rolling processes not only lead to distinct microstructures but also result in different local variations in composition. The warm-rolling may be a way to improvethe combination of strength and ductility compared to the cold-rolled counterparts. In summary, the findings of this study suggest that warm-rolling can be effectively employedas a thermo-mechanical approach for tailoring the microstructure and mechanical properties of the CrMnFeCoNi alloy, as well as other single-phase FCC high entropy alloys(HEAs).

High entropy alloys with fixed fcc-structure forhydrogen storage

Michael Felderhoff[1], Frederik Winkelmann[2], Mateusz Balcerzak[2], Gero Padberg[2]

[1]Max-Planck-Institut für Kohlenforschung (*Heterogeneous Catalysis*) , [2]Max-Planck-Institut für Kohlenforschung

e-mail: felderhoff@mpi-muelheim.mpg.de

Alloys with at least five principal elements with atomic concentrations between 5 and 35% are called high entropy alloys (HEAs). This mixing often lead to the formation of simple single-phased solid solutions with body centered cubic structures. During hydrogenation, a phase transformation from the bcc to the fcc structure (face centered cubic) is often observed, with an increase of the unit cell and a volume expansion of the material in the macroscopic state. This swelling process can lead to various problems in the design of tank systems for solid metal hydrides. One possible option to prevent this process is to fix HEAs in the fcc-structure so that significant volume expansion cannot occur during hydrogenation. The synthesis and properties of fcc-fixed HEAs are demonstrated using various examples.

Hydrogen induced failure in Ti6Al4V0.1Ru alloy

e-mail: barbaragn10@poli.ufrj.br

The challenge of exploring oil in extreme conditions, which includes the presence of gaseous CO2 and H2S and a deepwater salt layer, has led the material design of metallic components towards increasingly special alloys. In addition to high mechanical and corrosion resistance, these alloys must exhibit the resistance to hydrogen embrittlement caused in service. Hydrogen embrittlement is a major industrial problem, as it can occur in several metal alloys that are mechanically and corrosion resistant, such as nickel alloys (I718, I725), duplex, superduplex steels, among others. In this scenario of numerous attempts to search for alloys adapted to aggressive environments, titanium alloys of high specific mechanical strength and fatigue resistance, have been explored. It is noteworthy that titanium alloys still exhibit low density (d= 4.7g/cm3) when compared to Ni base alloys (d= 8.9 g/cm3) and Fe (d= 7.8 g/cm3). To achieve high mechanical properties, alloying elements should be added to titanium so that alloys with biphasic structure (α = HC and β=BCC) are obtained. Ti and Ti-based alloys form hydrides with hydrogen and become brittle. Thus, components made of these materials are coated with elastomer to avoid hydrogen embrittlement. In case of any rupture in this layer, the alloy may be in contact with hydrogen sources and be subjected to hydrogen embrittlement. In this context the present work aims to evaluate the hydrogen permeation and thermal desorption spectroscopy, together mechanical properties in the samples hydrogenated to elucidate the mechanism of degradation induced by hydrogen in Ti6Al4V0.1Ru.

Materials costumization by In-situ synthesis ofadvanced alloys

Ana Sofia Clímaco Monteiro D' Oliveira[1] [1]Universidade

Federal do Paraná (*Engenharia Mecânica*)

e-mail: sofmat@ufpr.br

A major contribution to a sustainable manufacturing chain is offer by a deep knowledge of the tripod processing/microstructure/performance. High efficiency of materials usage and an understanding of high performance materials and parts fabrication is a major step to a sustainable industry. Enhanced performance can be achieved with costumized materials for each application leading to longer service life a reduced industrial waste, particularly for parts operating under harsh conditions, such as high temperature applications where multiple phenomena act on the material simultaneously. In-situ synthesis of low weldability alloys to process protective coatings or parts by additive manufacturing during the deposition of powder mixtures presents adequate features to costumize parts. A competitive route to costumize materials is summarized and discussed, particularly for the in-situ processing of intermetallic alloys. The solidification of intermetallic processed by plasma transferred arc as single layer and multilayer deposits and the impact of the interaction with the substrate is discussed for nickel aluminides well known for their advanced performance. The impact of the interaction with the substrate in the ordered alloy that accounts for a higher hardness and it effect on high temperature wear is shown. Compositional and property gradients obtained from in-situ synthesis during multilayer processing allowing to process sound materials with either smooth or sharp gradients. Examples of carbide gradient in an aluminide matrix and the simultaneously synthesis of aluminide and ceramic layers are analyzed and their impact on wear performance discussed. Highlights from recent developments on the synthesis of Nb silicides and the challenge of in-situ processing multi-element compositions are discussed regarding its impact on a wider use of Nb alloys.

Mechanical deformations as a way to enhance hydrogen storage properties of metal hydrides

Jacques Huot[1]

[1]Université du Québec à Trois-Rivières (*Chemistry, Biochemistry and Physics*)

e-mail: jacques.huot@uqtr.ca

Metal hydrides are attractive materials for a large range of hydrogen storage applications. However, a few characteristics have to be improved in order to make them more commercially suitable. In this talk we will review various mechanical deformation techniques that could enhance the hydrogen storage properties of metal hydrides. Cold rolling (CR), Equal channel Angular Pressing (ECAP), High-Pressure Torsion (HPT), and Ball Milling (BM) will be covered. The characteristics of each of these techniques will be discussed. Different examples of these techniques on a wide range of metal hydrides (Mg-based, LaNi5, TiFe, BCC alloys and High Entropy Alloys (HEA) will be shown.

Metal-based nanoparticles supported on date seed-activated carbon as electrocatalysts for the conversion of biomass derivatives into biofuels

Muhammad Ashraf Sabri[1], G. Bharath[1], Abdul Hai[1], Mohammad Abu Haija[2],
Ricardo P. Nogueira[1], Fawzi Banat[1]

[1] Department of Chemical Engineering, Khalifa University, [2] Department of Chemistry, Khalifa University

email: Ricardo.Nogueira@ku.ac.ae

The conversion of biomass derivatives into biofuels through electrocatalysis is an effective and environmentally friendly method. To achieve selective production of biofuels, it is crucial to develop eco-friendly, robust, and sustainable electrocatalysts. This presentation showcases the results of nanoparticles deposited on date seed activated carbon supports, prepared and characterized using various analytical methods. The catalyst structure was analyzed through SEM,EDX, and X-ray diffraction, revealing that the metallic nanoparticles were successfully incorporatedinto the date seed activated carbon's disordered graphite-like structures. By simultaneously electrochemically hydrogenating (ECH) and oxidizing (ECO) furfural-based compounds, valuable biofuels such as furfural alcohol were obtained from biomass conversion. The electrocatalytic activity of the different catalysts was determined through cyclic voltammetry and electrochemicalimpedance spectroscopy. Catalysts were used with varying metal and content ratios to adjust furfural's ECH and ECO, resulting in different product yields and selectivity while also reducing the competing hydrogen evolution reaction. This study highlights the potential of converting biomassderivatives into biofuels to produce renewable energy.

e-mail: matheuspw.unicamp@gmail.com

One of the main motivations for carrying out eutectic growth study is the possibility of developing in-situ composite materials with special features, which provides an opportunity of merging the properties of distinct constituents into one material. The exciting microstructures found in several eutectic alloys result from cooperative growth, which is connected to the atomic transfer in the melt ahead of the solid/liquid interface. The features of intermetallic NiAl compound, with a B2 structure and a relatively low density and high oxidation resistance, melting temperature, hardness, and chemical stability make it an attractive material for the replacement of Ni superalloys. However, like many other intermetallic compounds, it shows poor ductility and low fracture toughness at room temperature. A strategy to address its lack of ductility while maintaining its mechanical strength is to combine it with another phase in the form of composite materials. The high-entropy alloys (HEAs) offer a new perspective to produce in-situ composites that are made up of brittle NiAl and a ductile phase, in which both phases are produced simultaneously during the solidification of a eutectic HEA (EHEA). In this context, this work explores the growth mechanisms of the two EHEA, AlCoCrFeNi2.1 (L ↔ NiAl-rich+ CoCrFeNi-rich) and Al0.8CrFeNi2.2 (L ↔ NiAl-rich+CrFeNi-rich) using directional solidification. The directionally solidified samples of both compositions exhibited a well-aligned microstructure with a lamellar morphology, regardless of the growth rate employed. The mechanical behavior of both EHEAs was assessed by compressive and Vickers hardness tests, and the results suggested that they exhibited remarkable mechanical behavior.

e-mail: daniel.leiva@ufscar.br

Hydrogen is an abundant and a promising energy carrier for cleaner energy applications. Therefore, solid-state hydrogen storage technologies using nanostructured materials is an important field of study. High gravimetric capacity and low cost make Magnesium-based alloys promising hydrogen storage materials, especially for stationary or electrochemical applications. Mg_2Ni has been extensively studied because of its relatively low enthalpy of formation. For the Mg_2Ni - based alloys, fast absorption kinetics at around 300 °C are usually obtained through complex routes, such as hydriding combustion synthesis or production of nanoparticles. In this study, we obtained Mg_2NiH_4 hydrides by reactive milling, annealing heat treatments and hydrogen absorption/desorption cycles at 350°C. Through this processing route, we obtained highly reactive hydrogen storage Mg_2Ni alloys, able to absorb and desorb hydrogen at temperatures lower than 300 °C, with desorption kinetics similar to those of alloys obtained by nanoparticle production or hydriding combustion synthesis and even better optimized absorption capacity. For example, a Mg_2Ni sample obtained by one of the routes investigated here showed hydrogen absorption capacity of 3.0 wt.% at 250 °C, with 2.5 wt.% absorbed in less than 50 seconds. A relevant surface protection effect of polyetherimine (PEI) introduced by solution mixing was confirmed for samples air-exposed for 01 day, 01 week and 01 month. Funding by FAPESP (The São Paulo Research Foundation) through process number 2019/20273-8 is greatly acknowledged.

QUick x-ray Absorption spectroscopy for TIme and space-resolved experiments: Opportunities for researchin energy materials

Santiago J.A. Figueroa[1], Amelie Rochet[2], Igor Ferreira Torquato[2], Alexey Marques Espíndola[2], Murilo F. Oliveira[2]

[1]Brazilian Center for Research in Energy and Materials (*LNLS*) , [2]Brazilian Center for Research in Energy and Materials (***Brazilian Synchrotron Light Laboratory***)

e-mail: santiago.figueroa@lnls.br

In this talk, we will present the opportunities offered by QUATI beamline (QUick x-ray Absorption spectroscopy for TIme and space-resolved experiments) to research energy materials. The beamline is under construction at the 4th generation Brazilian synchrotron source Sirius [1]. QUATI will be dedicated to high-quality hard X-ray absorption spectroscopy for time and space resolved experiments under in situ/operando conditions. Thanks to the high intensity of photons and low emittance obtained from 4th generation facilities of synchrotron, fast acquisitions are expected, which are crucial for the study of dynamic processes.

The beamline’s design has focused on a high flux of photons in a wide energy range, 4.5-35keV (i.e. allows XAS from Ti to Xe in K edge other higher Z elements in L edges), with flexibility in beam (10’s μm to mm) and with focus towards a combination of multi-techniques. Taking advantage of the high flux of hard X-rays, it will be possible to perform not only conventional XAS measurements, but also spectro-tomography, high resolution -XAS and X-ray emission spectroscopy with dedicated instrumentations. Besides, a complete samples infrastructure is proposed to perform true operando characterizations with the combination of techniques, such as Raman, Infrared and X-ray diffraction. Finally, special attention has been dedicated to developing new software tools for the treatment of a large amount of data with multivariate analysis.

Solidification Behavior of Metallic Alloys by Selective LASER Melting

Brenda Juliet Martins Freitas, Leandro Henrique Pereira, Walter José Botta Filho
Claudemiro Bolfarini.

Additive Manufacturing is an emerging industrial process based on selective laser melting of metallic alloys. Due to the very fast cooling rates (10^5 K/s) prevailing during solidification the microstructure presents micro/nanosegregation at cellular/dendritic boundaries and supersaturation of the matrix. The distribution of the alloying elements in this particular microstructure presents very special features that must be tailored to optimize the properties of the components. In this talk some results for AlSiMg-Fe alloy and Duplex Stainless steel are presented in order to highlight the magnitude of segregation , correlations with the estimated solidification rates and the effect of postprocessing heat treatments on the microstructure and properties

The estimation of the surface plastic deformation produced by grit-blasting in maraging steel using the strain-induced γ-α' transformation phenomena

José Carlos Fortes Palau[1,2], Dilermando Nagle Travessa[1]

[1]Universidade Federal de São Paulo (*Ciência e Tecnologia*) , [2]Instituto de Aeronáutica eEspaço (*Ciência e Tecnologia Aeroespacial*)

e-mail: jpalau@unifesp.br

Grit-blasting is a treatment used in many industrial applications for cleaning and preparing metallic surfaces. Plastic deformation is induced by the high-velocity abrasive particles on the blasted metal surface, which may change mechanical properties in service. The quantification of such induced plastic strain is a difficult task, as the deformation mechanism involved in grit-blasting is complex. In quenched maraging steels, overaging leads to the transformation of martensite into reverted γ-austenite, which can be mechanically re-transformed into martensite by deformation at room temperature. This phenomenon can be used to estimate the plastic strain induced by grit-blasting. In the present study, overaged 18Ni(300) maraging steel samples were blasted at two different blasting angles (45º and 75º), keeping all other variables controlled at constant levels. The kinetics of γ-austenite into α′-martensite transformation was treated as a function of the strain, according to the Ludwigson-Berger model, parametrized by an experimental constant (Kp), related to the mechanical stability of the reverted γ-austenite and obtained from controlled uniaxial stretching testing at controlled deformation levels. The increase on the dislocation density (ρ) resulting from blasting could also be determined, by the Williamson-Hall method. The volume fraction of γ-austenite (fγ) was quantified in both blasted and stretched samples by ex-situ XRD analyses. It was found that α′-martensite was formed in blasted and stretched samples due to plastic deformation, after certain stress levels. Differences in strain rate between blasted and stretched samples and the consequent adiabatic heating effect on the kinetics of α′-martensite transformation were discussed. The true surface plastic strain induced by grit-blasting was estimated at 0.031 and 0.047 for blasting angles of 45º and 75º, respectively.

Advanced ferrous alloys and coatings for demanding applications

Guilherme Yuuki Koga[1], Claudemiro Bolfarini[1], Claudio S. Kiminami[1], Alberto Moreira Jorge Junior[1], Walter Botta[1]

[1]Univerdade Federal de São Carlos

e-mail: gykoga@ufscar.br

Ferrous alloys are the first choice among metallic materials given a myriad of possibilities to design its structure in different length-scales to meet strict requirements. It is notorious the importance of steels on the success of developing modern societies. Iron (Fe) and its alloys are essential for improving the quality of life and enabling affordable and mass use technologies. Strength and toughness are vital requirements for most structural applications but are often mutually exclusive. Steel metallurgy proved to surpass this conflict through technologies at a reasonable cost, and research over the decades has enabled unprecedented levels of mechanical properties, including damage tolerance. Besides the economic and structural aspects, wear and corrosion resistance are also basic attributes of alloys aiming to withstand aggressive environments. In some cases, having corrosion and wear resistance is the first criterion for materials selection. This work summarizes the progress of advanced ferrous alloys and coatings in terms of alloy design, powder production, protective coatings, and how the microstructural features dictate the basket of properties, with focus on the tribological and electrochemical aspects.

e-mail: angelo.andreoli@ufscar.br

The linear coefficient of thermal expansion and specific heat capacity at a constant pressure of medium-entropy CrFeNi and CoCrNi alloys, as well as CoCrFeNi high-entropy alloy, showed an abnormal behavior in the temperature range 700-950 K. Magnetic moment measurements as a function of temperature demonstrated that the observed discontinuities are unrelated to the Curie temperature. The structural and microstructural alterations caused by heat treatments were studied in samples with varying thermal histories. According to transmission electron microscopy (TEM) and synchrotron X-ray diffraction data, second-phase precipitation, recrystallization, and texture are also not to blame. X-ray absorption fine structure shows that local lattice distortions are insignificant and that Cr and Ni elements have an unusual interaction. Combining the results of near-edge X-ray absorption fine structure and X-ray photoelectron spectroscopy indicates a pseudo-gap valley, which means a decrease in the overall Density of States at the Fermi energy upon alloying, with Cr and Ni being the primary contributors. The observed anomalies in thermophysical characteristics are attributed to chemical short-range order, also known as the K-state effect.

The Renato Archer Information Technology Center, through its Coordination of Technological Park and Open Laboratories (COLAB), will make available to Brazilian researchers a recently acquired Bruker/Skyscan 1272 CMOS X-ray microtomography equipment. Our first initiative was to perform a six-month pilot project aimed at creating a service protocol adapted to COLAB rules from project proposal submission to results delivery. A large variety of samples with different shapes, chemical compositions, and sizes were employed, including teeth, insect parts, microelectronic boards, 3D printed polymer, ceramic and metal parts, metal powder, and composite materials. The Bruker proprietary software for reconstruction (NRecon), visualization (CTVol, CTVox), and analysis (CTan) were utilized. The FileSender@RNP public interface was tested for sending large data archives. Additionally, the free software InVesalius, developed by CTI, was tested for providing users with basic measurements, segmentation, and visualization tools. We also tested remote access to software installed in CTI workstations for advanced reconstruction and measurements that require high computational processing. A preliminary protocol states that remote access to CTI workstations can be done satisfactorily but it is necessary to increase the computational capabilities of the CTI, even for a small number of users, to store the large amount of data that is generated. FileSender@RNP public interface worked well to tranfer large archives to the computer users. Data security measures should restrict access to users' data only. Concerning the samples, the metal ones must be small and thin, and those with low density should have transmission rates above 20%. Finally, the CTAn analysis is the user´s responsibility. Operating the X-ray microtomography equipment requires a 48-hour in-person training course.Acknowledgments:FINEP and CNPq for financial support References:[1] Bruker website , Skyscan 1272

Chromium carbides dissolution and corrosive attack on the surface of an AISI 430 stainless steel after heat treatment in different temperatures

Fabrício César de Mendonça Cordeiro[1,2], Leandro de Arruda Santos[1], Wilian da Silva Labiapari[2]

[1]Universidade Federal de Minas Gerais, [2]Aperam South America

e-mail: fabricio.cordeiro@aperam.com

Non-stabilized stainless steel AISI 430 presents chromium carbides in its microstructure that are dispersed in the ferritic matrix of the steel. Depending on the thermal cycle used in the steel, these carbides preferentially precipitate in grain boundaries [1], generating a region pour in chromium next to them, what is a sensitization process[2]. These sensitizedregions are more susceptible to corrosive attacks [3]. This way, chromium carbides dissolution in AISI 430 had been evaluated after heat treatments in different temperaturesas well as what was the influence on the material's surface microstructure after corrosiveattack. After an initial characterization, hot rolled and annealed samples had been heat treated in an electrical furnace. Temperatures varied from 750 to 1050°C, in 80s cycles andwith fast cooling. From 950°C on, there is a decrease in the amount of carbides as the temperature of heat treatment increases. From 1000°C on, there is an increase in materialhardness and martensite is present in the microstructure. The heat treated samples hadbeen attacked with sulfuric acid and it was observed that the higher the heat treatment temperature, the smaller was the corrosive attack.

e-mail: brunohesselpgb@gmail.com

Implementing hydrogen as an energy carrier to decarbonize industry applications might be very challenging. In this context, metal hydrides are a suitable option for solid state storage applications. Recently, Ti-V-Nb-Cr body-centered-cubic (BCC) alloys have shown promising storage properties including the ability to absorb hydrogen without the need of an activation treatment. However, the obtention of a Ti-V-Nb-Cr BCC alloy that absorbs/desorbs hydrogen at moderate pressure/temperature conditions with easy activation and cycling stability remains a challenge. In the present work, we demonstrate an approach to design a Ti-V-Nb-Cr BCC alloy with hydrogen absorption/desorption reversibility at room temperature and moderate pressure. CALPHAD (Calculation of Phase Diagrams) method and a thermodynamic model [1] to calculate pressure-composition-temperature (PCT) diagrams were employed to find compositions prone to form BCC alloys with plateau pressures above 1 bar at room temperature. Three BCC Ti-V-Nb-Cr alloys were synthesized via arc melting and showed the capacity to absorb hydrogen with fast kinetic and without activation treatments. PCT diagrams demonstrated reasonable agreement with the predicted diagrams calculated via modelling. Moreover, one of the designed alloys (Ti11V30Nb28Cr31) showed the capacity to reversibly absorb/desorb ~1.7 wt.% of H at room temperature and moderate pressure conditions. These results are unprecedent for the Ti-V-Nb-Cr system and emphasize the importance of alloy design strategies via computational tools.

The nanocomposites formed by crystalline $NiSi_2$ and $CoSi_2$nanocrystals embedded in silicon wafers have attracted the attention of many researches due to the potential of its application in nanotechnology. In this study we describe the effect of thermal treatment temperatures on the final size of well oriented $NiSi_2$and $CoSi_2$nanoplates grown in Si(001) wafers in a thin layer close to its external surface. The preparation of the silicide nanocrystals consisted in the deposition of a solution of Ni and Co salts on bare Si wafers, to obtain the $NiSi_2$and $CoSi_2$nanoplates, respectively, followed by thermal treatments of the samples under H_2flow at temperatures favorable to the diffusion of the Ni and Co atoms from the thin film into Si wafers and subsequent reaction with Si atoms. It was observed that this preparation method results in the formation of $NiSi_2$and $CoSi_2$silicide nanoplates with the shape of nearly regular hexagons having their larger surfaces parallel to one of the planes of Si{111} crystallographic form [1,2]. Samples on which salts of Ni or Co were deposited were annealed at different temperatures in the 340-700 °C range during 1 h. The average thickness and lateral side of the hexagonal silicide nanoplates formed in Si were determined from the analysis of grazing-incidence small-angle X-ray scattering (GISAXS) measurements performed after the thermal treatments.

Medium/high entropy, Multiprincipal element alloys (MPEAs) have significantly increased the number of potential compositions of metallic alloys to unprecedented levels. In additionto discovering new compositions of interest, optimizing the most promising MPEAs is equally critical. The $Cr_{40}Co_{40}Ni_{20}$MPEA stands out by showing a high mechanical strengthening via grain refining, and high work hardening capacity, resulting from the strain-induced HCP phase formation (TRIP effect) [1]. An important optimization route is the use of interstitial elements as microstructural refiners [2,3], which should be especially advantageous in alloys that have high sensitivity of mechanical properties in relation to grain size, such as CrCoNi MPEAs. Therefore, the objective of this work is to study the effect of interstitial elements (C and N) on the phase equilibrium, grain refinement and mechanical behavior of $Cr_{40}Co_{40}Ni_{20}$MPEA. The base alloy, two compositions with N, and two with C were selected by the CALPHAD method, produced with high purity elements, and annealed at four different temperatures. Microstructural analysis and hardness tests were carried out. The interstitial elements, either in solid solution or in the form of carbides and nitrides, had an influence on phase stability, recrystallization onset, grain refinement and hardness. In-situ tensile tests using synchrotron radiation were performed on some samples. The influence of interstitials on mechanical properties, stacking fault energy and deformation mechanisms are discussed.

Exploring the Compositional Flexibility and Mechanical Properties of Multi-Principal Element Alloys

Francisco Gil Coury[1]

[1]Univerdade Federal de São Carlos (*Engenharia de Materiais*)

e-mail: fgcoury@ufscar.br

Multi-Principal Element Alloys (MPEAs) are alloys that do not have a single principal element, and therefore encompass an immense number of possible compositions. In terms of mechanical behavior, some compositions with a range of interesting properties have been discovered. Notable compositions reported include those of the Cr-Co-Ni, Fe-Mn-Cr-Ni, and Co-Ni-V systems, which are among the toughest materials ever developed. This high toughness can be attributed to the various hardening and deformation mechanisms of this material when subjected to mechanical stress. The fact that these alloys have a very large compositional flexibility makes it impractical to propose new compositions by trial-and-error methods. In this work, a series of results will be presented that have been carried out by our research group to efficiently explore this large compositional field. Models will be presented that are used to a priori understand the potential of a certain composition for structural applications. These models include the prediction of phases formed in the alloy, as well as the prediction of hardening and deformation mechanisms. Experimental results of the validation and comparison of these models will be presented, as well as how this type of methodology can lead us to deepen our fundamental knowledge of hardening and deformation mechanisms in concentrated metallic alloys. Great emphasis will be given to Cr-Co-Ni compositions, refractory alloys, and precipitation-hardenable alloys, three classesof alloys that have been extensively studied in the literature of HEAs. Ideas and paths forthe development of these alloys will also be discussed.

Highly porous CP-Ti foams manufactured with powder compaction, the space holder method and plasma-assisted sintering for biomedical applications

Francisco Cavilha Neto[1], Cristiano Binder[1], Aloisio Nelmo Klein[2], Claudio Aguilar[3], Vicente Salinas Barrera[4]

[1]Universidade Federal de Santa Catarina (*Engenharia Mecânica*) , [2]Universidade Federal de Santa Catarina, [3]Universidad Técnica Federico Santa María (*Departamento de Ingeniería Metalúrgica y de Materiales*) , [4]Universidad Autónoma de Chile (*Facultad de Ingeniería*)

e-mail: franciscocavilha@gmail.com

Highly porous titanium foams are components used to replace bone structures with low elastic modulus due to their ability to avoid the phenomenon called stress shielding. The porous structure with a volume of over 70% reduces the elastic modulus of the component to values closer to that of trabecular bone, mimicking the mechanical characteristics of the structure being replaced. However, producing foams with porosities above 70% using space holders is challenging because the component can collapse during processing due to the high amount of temporary material. In this study, pure titanium powder was mixed with 50, 70, and 80 volume percent KCl as a space holder, cold-compacted, and sintered at 1250 °Cin a tubular furnace to obtain foams with high porosity. The space holder was removed inthe same furnace by sublimation prior to sintering. The porous architecture of the foams was analyzed through image analysis. The elastic modulus of the foams was measured using Ultrasonic Waves Transmission (UWT), a non-destructive method of mechanical characterization that is commonly applied to bulk materials and has great potential for exploring foams. The results showed an influence of the amount of space holder on pore , form and distribution. The elastic moduli measured in all samples with 80% porosity were equivalent to those of trabecular bone.

Hydrogen Storage Properties of the TiVFeZr Multicomponent Alloy

Vinícius Aranda[1], Daniel Rodrigo Leiva[2], Jacques Huot[3], Walter Botta[2], Guilherme Zepon[2]

e-mail: viniciusaranda@estudante.ufscar.br

Hydrogen as an energy vector is one of the possible solutions to the widespread use of renewable energy sources. Intermetallic-based multicomponent metal hydrides have been widely studied to storage hydrogen, such as TiZrCrMnFeNi[1], (ZrTiVFe)xAly[2] and ZrTiVAl1-xFex[3]. In this work, the structure and hydrogen storage properties of the TiVFeZr multicomponent alloy synthesized by arc melting was comprehensively investigated. The TiVFeZr alloy solidified forming a single C14-type Laves phase structure. This alloy presents fast hydrogen storage kinetics at room temperature with high hydrogen storage capacity, absorbing H/M = 1.5 (2.41 wt.%) in less than 100 s under initial hydrogen pressure of 20 bar. This is one of the highest hydrogen storage capacities among the Laves phase alloys reported to date. The formed hydride is highly stable, which demands temperatures above to 550 °C to completely desorb hydrogen. The high hydrogen storage capacity of this alloy as well as the high stability of the formed hydride are discussed in terms of the high fraction of hydride forming elements in the C14-type Laves phase structure.

Individual effect of Y and Nd on the microstructure formation of Mg-Y-Nd alloys processed by severe plastic deformation

Peter Minarik[1], Maria Zemkova[2], Jan Dittrich[2], Jan Bohlen[3], Robert Kral[2]

[1]Charles University (*Department of Physics of Materials*) , [2]Charles University, [3]Helmholtz-Zentrum Hereon

e-mail: peter.minarik@mff.cuni.cz

The effect of sole yttrium and neodymium alloying on the microstructure formation during severe plastic deformation by equal channel angular pressing (ECAP) was investigated. The results are compared with a ternary Mg-4Y-3Nd alloy, which represents a simplified version of the commercially successful WE43 alloy. It is shown that the presence of Nd primarily caused precipitation during the processing of the Mg-3Nd alloy, while Y remained dissolvedin the magnesium matrix in the Mg-3Y alloy. This difference resulted in a significantly smaller average grain size in the Mg-3Y alloy (~0.77 nm) than in the Mg-3Nd alloy (~1.3μm) after the final step of the processing and formation of a slightly different texture. Consequently, the composition and the processing affected the mechanical and corrosionproperties of the investigated materials. It is shown that the ECAP-processed W3 sample exhibits a surprisingly good combination of ultrafine-grain structure, weak crystallographictexture, high strength, and high corrosion resistance compared with the other investigatedsamples. These attributes make this material very interesting for utilisation in the industry and/or medicine.

Influence of solution annealing temperature on the microstructure of maraging 400 steels

Daniela Passarelo Moura da Fonseca[1], Angelo Fernando Padilha[2]

[1]Instituto Senai de Inovação em Processamento a Laser, [2]Universidade de São Paulo (*Escola Politécnica - PMT*)

e-mail: daniela.fonseca@sc.senai.br

Maraging 400 are a precipitation hardening steels whose base composition is Fe-13Ni-15Co-10Mo-1Ti (wt.%). In these steels, the annealing heat treatment needs to guarantee a solid solution and a martensitic microstructure, characteristics that provide the driving force for precipitation during aging [1-2]. For other classes of maraging steels (containing 18wt.% of nickel and lower contents of molybdenum and cobalt), the solution annealing treatment is very established (usually 820 °C for 1 h). However, the literature has indicated that for maraging 400 is required higher annealing temperature or time, due to changes in the chemical composition. [1-3]. The aim of this work was to study the influence of the annealing temperature on the microstructure of maraging 400 steels. The study were carried out on samples with five different compositions (varying molybdenum and titanium contents) solution annealed at 900, 1000 and 1200 °C for 1 h. Then, the samples were characterized by scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS), X-ray diffraction (XRD), electron backscatter diffraction (EBSD), dilatometry and Vickers hardness. The results indicated for an annealing temperature bellow 1000 °C, a microstructure containing undesirable Fe_3Mo micrometric precipitates. It was only at an solution annealing temperature of 1200 °C that it was possible to obtain a full martensitic microstructure. The molybdenum content influences the and amount of Fe_3Mo precipitates, as well as the phase transformation temperatures (of Fe_3Mo, austenite and martensite).

Mechanical properties and microstructure of biodegradable ultrafine-grained magnesium alloy processed by severe plastic deformation

Miloš Janeček[1], Jitka Stráská[2], Michaela Šlapáková[2], Jakub Čížek[2], Hyoung Seop Kim[3]

[1]Charles University (*Faculty of Mathematics and Physics*) , [2]Charles University, [3]Pohang University of Science & Technology

e-mail: janecek@met.mff.cuni.cz

Biodegradable magnesium alloy Mg22Gd alloy was processed by high pressure torsion (HPT, up to 15 turns) at room temperature and the pressure of 2GPa. Mechanical properties were investigated by detail 2D microhardness measurement. HPT straining introduces a lateral inhomogeneity in the material and resulted in inhomogeneous distribution of microhardness throughout disk specimens with the minimum in central zones and increasing values towards the specimen periphery. The microhardness was found to increase with increasing strain imposed by HPT and tend to saturate at about HV=145. The microstructure (grain size, phase composition, phase morphology, etc.) evolution with strain due to HPT was investigated by light and scanning electron microscopy and EDS. High Gd content in the alloy resulted in the precipitation of stable Mg5Gd phase. During straining the phase was continuously fragmented and only tiny particles were found in heavily strained particles.Electron back scatter diffraction (EBSD) and automated crystallographic orientation mapping in transmission electron microscope (ACOM TEM) were employed to characterize the fragmentation of the initial coarse grain structure with increasing strain. HPT was found to result in strong grain fragmentation of the factor of approximately 1000.High density of dislocations of the order of 10^14/m2 was found in individual specimens. The dislocation density was determined by enhanced techniques of positron annihilation spectroscopy and X-ray diffraction.The strength of the material was correlated with the dislocation density. It was shown that hardening during HPT is caused mainly by dislocation strengthening due to interaction of glide dislocations with forest dislocation as a result of relatively homogeneous distribution of dislocations in deformed specimens. Unlike in other magnesium alloys processed by severe plastic deformation the strengthening by grain refinement is negligible in MgGd alloy.

Microstructural and physical properties of commercial Nb-46.5wt.%Ti superconducting wires with different configuration strategies

Lucas Barcelos Otani[1], Tales Ferreira[2], Daniel Y. Kakizaki[2], Alan A. Vianna[2], Rafael Defavari[2], Rafael M. Seraphim[2], Osmar Roberto Bagnato[2], Lucas Barboza Sarno Da Silva[3], Durval Rodrigues Jr. [3]

e-mail: lucas.otani@ufscar.br

Commercial superconducting wires of Nb-46.5wt%Ti alloys are used in a diverse range of applications related to medical, transportation, and high energy physics. The microstructure is composed by the Nb-rich superconducting phase together with α-Ti precipitated in a nanocrystalline structure, acting as pinning centers. The wires consist of a Nb-46.5%pTi multifilamentary structure embedded in copper and, depending on the configuration strategy, this might lead to distinct superconductivity behavior. The bundling and the processing route generate distinct morphologies and microstructures and, consequently, superconducting properties, primarily the critical current density. The objective of this work is to characterize three different commercial superconducting wires to observe the microstructure and correlate with the superconducting properties. The microstructure was characterized by Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM). The SEM samples were prepared by mounting, grinding, and polishing; and the TEM samples by Focused-Ion Beam (FIB). The samples were characterized using a Physical Property Measurement System (PPMS) coupled with a Vibrating Sample Magnetometer (VSM), in which the characterizations were made to obtain the critical temperatures and the critical current densities at 4.2 K from loops of magnetization in moment vs. applied magnetic field curves.

Multicomponent Fe-based glass-forming alloysdeveloped for coatings applications

Diego Davi Coimbrão[1], Guilherme Zepon[2], Guilherme Yuuki Koga[2], Gabriel Pedrino[2], Claudio S. Kiminami[3], Claudemiro Bolfarini[3], Walter Botta[4]

[1]Universidade Federal de São Carlos (*Departamento de Engenharia de Materiais - DEMa*) , [2]Universidade Federal de São Carlos, [3]Univerdade Federal de São Carlos, [4]Univerdade Federal de São Carlos (*Engenharia de Materiais*)

e-mail: fdiego@ufscar.br

Fe-based glass-forming alloys are suitable to be used as coatings in steel components that require good corrosion and wear properties. We are using different strategies to design alloys with good compromise between these two properties, which are usually contradictories. In the present work we discuss the design strategies and the microstructural characterisation of multicomponent alloys of the following Fe-based systems: Fe-Cr-Ni-B, Fe-Cr-Mo-Nb-B, Fe-Co-Ni-Cr-Mo-B and Fe-Cr-Mo-Nb-B-C. The results show the important role and necessary balance played by the elements added to improve the glass forming ability, the ones added to improve the corrosion resistance and the ones that contribute to the formation of hard phases to improve the wear properties in partially crystallised alloys.

Nanostructured ceramic-metallic films produced by magnetron sputtering

Felipe Sampaio Alencastro[1], Olavo Teixeira Neto[2,3], Renata Antoun Simão[2]

[1]Universidade Federal do Rio de Janeiro (*Programa de Engenharia Metalúrgica e de Materiais / COPPE*) , [2]Universidade Federal do Rio de Janeiro (*Programa de Engenharia Metalúrgica e de Materiais*) , [3]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*DIMAT*)

e-mail: felipesa@metalmat.ufrj.br

This study dealt with the deposition of nanostructured ceramic-metallic thin films produced by magnetron sputtering. Three groups (Ti-Si-O-N, Al-Ti-C and Al-Si-N) were deposited froma mixture of metallic and ceramic sputtering targets (Ti and SiO2, Al and TiC, and Al and Si3N4, respectively). Ti-Si-O-N films were deposited seeking an application on solar collector system Al-Ti-C group was designed aiming an application on mirrors for heliostats used on solar concentrating system and Al-Si-N films were deposited seeking the hardnening of Al films. Deposited films were analyzed by transmission electron microscopy to evaluate its morphology. X-ray photoelectron spectroscopy (XPS) and Rutherford backscattering spectrometry (RBS) were used to determine the films chemical composition. The nanohardness of Al-Ti-C and Al-Si-N groups was evaluated, while samples from Ti-Si-O-N group were optically analyzed on ultraviolet, visible and infrared radiation ranges. Analyses results show that films from every group are formed by metallic nanocrystals embedded in an amorphous matrix, where both the volumetric fraction of nanocrystals and films hardness are dependent on the amount of deposited metal. Films from Ti-Si-O-N group showed nanoparticles only on the high metal fraction layer, linked to the thermal emittance of sample the low metal fraction layer, related to solar absorption, did not show metallic nanoparticles.

On the impacts of reactive high-energy ball milling onthe structural, microstructural, and hydrogen storage performance of refractory multicomponent alloys

Renato Belli Strozi[1,2], Guilherme Zepon[3], Walter Botta[4], Claudia Zlotea[5]

[1]Univerdade Federal de São Carlos (*Graduate Program in Materials Science and Engineering (PPGCEM)*), [2]Centre national de la recherche scientifique (*Graduate Program in Materials Science and Engineering (PPGCEM)*), [3]Universidade Federal de São Carlos (*Department of Materials Engineering*), [4]Univerdade Federal de São Carlos (*Engenharia de Materiais*), [5]Centre national de la recherche scientifique (*ICMPE*)

e-mail: renatobsf@gmail.com

Reactive high-energy ball milling (RBM) is a well-known technique for processing metal hydrides, often resulting in nanocrystalline materials with fast kinetics for hydrogen sorption. Thus, in this work, the influence of RBM processing on the structural properties ofa refractory alloy was investigated and correlated with hydrogen sorption properties. The TiVNbCr alloy was chosen since it has been extensively studied. The milled hydride was synthesized in two steps: (i) preparing the TiVNbCr alloy through arc melting; (ii) performing RBM under H_2pressure. The as-cast alloy crystallizes as a body-centered cubic (BCC) single-phase. Upon hydrogenation, the TiVNbCr alloy achieved a hydrogen-to-metal ratio (H/M) close to 2. Moreover, the XRD total scattering experiments followed by pair distribution function (PDF) analysis indicate that the hydrogenated alloy assumes a face-centered structure (FCC) typical for dihydride. Surprisingly, the X-ray experiments of the RBM hydride indicate a mixture of phases concerning a BCC monohydride and an FCC dihydride. The thermogravimetric analysis for desorption of the RBM powder indicates that the sample releases around 1.05 H/M. The comparison between the PDF analysis of the as-cast hydrogenated TiVNbCr alloy and the RBM hydride indicates that the reactive ball milling exerts a marked influence on the samples'' overall crystallinity, contributing to increasing the lattice defects and micro-strains. The accumulation of defects within the crystal structure can suppress the phase transformation from monohydride to dihydride, consequently diminishing the hydrogen uptake of BCC alloys [1]. Therefore, this work reveals the impact of ball milling on the structural characteristics of refractory high entropy alloys and proves its deleterious effect on their hydrogen storage performance.

e-mail: jessicabponsoni@gmail.com

Multicomponent alloys with C14 Laves phase are promising hydrogen storage materials due to their ability to reversibly absorb substantial amounts of hydrogen at room temperature with fast kinetics and improved cyclability [1]. The applicability of these alloys as a hydrogen storage media is governed by their thermodynamic properties, which can be tuned by the chemical composition design. In this regard, design methods with predictive properties modeling are essential for exploring the vast compositional field of multicomponent alloys. In this work, a computational approach was used aiming at a C14 Laves phase alloy for room-temperature hydrogen storage. First, CALPHAD method was applied to predict the phase formation of the AB_2-type alloy compositions. Secondly, a model to predict the thermodynamics of the metal-hydrogen systems was proposed to calculate the pressure-composition-isotherm (PCI) of multicomponent C14 Laves phase alloys [2]. According to the design, the $(Ti_{0.5}Zr_{0.5})_1(Fe_{0.33}Mn_{0.33}Cr_{0.33})_2$alloy would solidify as a single C14 phase and would be capable of storing hydrogen reversibly due to the calculated hydrogen equilibrium pressure in the order of 10^1bar at 30 °C. The alloy was produced by arc-meltingand experimentally characterized by structural and volumetric techniques. X-ray diffraction analysis indicated the formation of a single C14 Laves phase. PCI diagram showed that the alloy reversibly stored 1.7 wt.% (H/M = 1) of hydrogen with fast absorption and desorption kinetics at 30 °C up to 100 bar. Furthermore, the alloy showed great cycling stability over50 cycles at 30 °C, exhibiting excellent reversible hydrogen storage properties.

Seven decades of Hall-Petch: background and current trends

Roberto B. Figueiredo[1]

[1]Universidade Federal de Minas Gerais (*Departamento de Engenharia Metalúrgica e de Materiais*)

e-mail: figueiredo@demet.ufmg.br

The relationship between grain size and mechanical strength has been studied for many decades. An important step forward in this area was achieved seven decades ago with the publication of papers which pointed that the yield stress of mild steel is proportional to the inverse of the square root of the grain size. Similar trends have been reported for other metallic materials and this relationship has been accepted until the present days. The phenomenology behind this relationship is not clear yet though. Many mechanisms have been suggested to explain it but none of these mechanisms has been supported by a large amount of experimental data for different materials. There has also been disagreement regarding the thermal-activated nature of this effect and its validity for a broad range of grain sizes including nanocrystalline materials. The present study reviews the developments in this field of study and the recent advances which include large amount of data for materials with nanocrystalline structure and advanced characterization techniques. It is shown that the ability to produce samples with very small grain sizes, which was developed in recent decades, shed light in this topic and many trends are clearer now. It is also shown that a recently developed model display the best agreement with experimental data for approximately 30 different metals and alloys, tested at different strain rates and temperatures. The trends of grain refinement hardening at low temperatures and grain refinement softening at high temperature are both explained by this model.

Solubilization and aging heat treatments of aluminum alloy 5083 with Microstructural analysis via FEG-EBSD

Eloam Jéssica Nunes Holanda[1], Mauricio Mhirdaui Peres[1], Nicolau Apoena Castro.[2]

[1]Universidade Federal do Rio Grande do Norte (*Engenharia de Materiais*) , [2]Federal University of Rio Grande do Norte - UFRN

e-mail: eloam.holanda.077@ufrn.edu.br

The evaluation of the compositional and microstructural characteristics of alloy 5083 subjected to solubilization and aging at different combinations of temperature and time, aims to develop thermal procedures in the recovery of this alloy that is susceptible to sensitization [1] in its application. Heat treatments were carried out on samples of alloy 5083 H112 sheet. Solubilization took place at 450ºC and 500ºC, with a soaking time of 2 hours and followed by cooling in water, and aging took place at 180ºC with soaking times of1, 3, 6 and 9 hours followed by air cooling. Then, the samples were evaluated via X-ray diffraction (XRD) and scanning electron microscopy (SEM-FEG with EDS and EBSD), in order to evaluate the most favorable microstructures for sensitization, by controlling the amount and of precipitates rich in Mg. It was observed in the original sample, partially work hardened, signs of incomplete recrystallization, a small amount of precipitates rich in Mg and grains of Al-α with a high content of magnesium in solid solution, indicating a metastable state, which prevailed in the samples. solubilized, as expected. In addition, the presence of coarse precipitates of Al6Fe was noticeable. Regarding the solubilized samples, they showed growth of thermally activated grains and incomplete recrystallization. The samples aged under different conditions, on the other hand, showed a greater amount of precipitates compared to the others, promoting a state closer to equilibrium as a function of temperature and soaking time.

Strategies to design multicomponent metal alloys for different hydrogen storage applications

Guilherme Zepon[1], Renato Belli Strozi[2], Bruno Hessel Silva[3], Jéssica Bruna Ponsoni[3], Otávio Abreu Pedroso[4], Walter Botta[2]

[1]Federal University of Sao Carlos (*Materials Engineering Department*) , [2]Univerdade Federal de São Carlos (*Materials Engineering Department*) , [3]Univerdade Federal de São Carlos (*Graduate Program of Materials Science and Engineering*) , [4]Federal University of Sao Carlos (*Graduate Program of Materials Science and Engineering*)

e-mail: zepon@ufscar.br

Hydrogen has a central role in the fight against the climate change by being an excellent energy vector to store and transport renewable energy. Metal hydrides (MHs) are suitable candidates to store and transport hydrogen in solid state with high volumetric energy density. In the past few years, many attentions to multicomponent alloys that form multicomponent metal hydrides (MCMHs) have been given because of the possibility to tailor their hydrogen storage properties by compositional control. However, navigating the endless compositional field of multicomponent phase diagrams and finding the composition and phases with optimized properties is not a simple task. In this work, we present three alloy design strategies that were successfully employed to find MCMHs compositions with suitable properties for different applications. The first strategy was based on calculation of geometrical, electronic, and thermodynamic parameters that allowed us to design a BCC single phase Mg-containing MCMHs. The second and third strategy were based on thermodynamic calculation using CALPHAD method coupled with pressure-composition-temperature (PCT) diagram calculation using models developed by our research group. The second strategy was used to design BCC single phase alloys with tunable hydrogen absorption/desorption plateau pressure. Finally, the third method was employed to design single C14-type Laves phase intermetallics also with tunable hydrogen absorption/desorption equilibrium pressure. The three design strategies were experimentally verified by synthesizing the designed alloys with an appropriate method, followed by structural characterization and hydrogen storage properties measurements. e-mail: cristiane.goncalves@villaresmetals.com

Plasma nitriding is a thermochemical process of technological importance to reduce damage on the steel surface, improving die life. To the aluminum die casting die industry, the most important advantage is to improve its tribological characteristics, due the increase in surface hardness and the presence of residual compression stresses were able to slow down cracking, erosion / etching of aluminum and wear in the regions of the feed channels. However, the properties of this layer may change, due to the conditions of use of the die. The industrial environment submitted the nitrided surface to temperatures up to 600°C and, in the literature, there is not a clear understanding of the microstructural stability of nitrided surface properties. Therefore, the aim of this study is to evaluate the effect of temperature on the nitrided layer of AISI H13 steel, which is used by the industry for making dies and molds used in the hot forming or casting process of non-ferrous alloys. Samples were hardened and tempered to 45 HRC and then nitrided aiming for a layer with adepth up to 100 μm, without white layer. After nitriding, some samples were annelead in afurnace at 600°C for 30min, 2h, 5h, 10h and 100h. Some samples were tested formicrostructure, x-ray diffraction and residual stress. The nitrated layer, after being subjected to high temperature, presents a reduction of level in the residual tensions of compression, bringing about a process of tensions relief. The same effect is not so stronglyverified in the material hardness profile. Additional tests as chemical mapping of some elements through WDS techniques and characterization of nitrides particles high-resolution scanning electron microscopy, FEG, was important in this study to better understanding themicrostructure stability of the of the nitrated layers when exposed to higher temperatures.

The effect of Al, Cr and Mo additions in NbTiSiZrcoatings

Eloisa Pereira Cardozo[1], Ana Sofia Clímaco Monteiro D' Oliveira[2] [1]Universidade Federal do Paraná (*Tecnologia*) , [2]Universidade Federal do Paraná (*Engenharia Mecânica*)

e-mail: elocrdz@gmail.com

Since the early 1990s, Nb-Si intermetallic based alloys are seen as potential candidates for ultra-high temperature structural applications [1]. The development of innovative manufacturing techniques and the addition of multiple alloying elements to niobium-silicide alloys are considered mandatory to reach physical and chemical property goals [2]. This investigation takes an important step to process sound Niobium alloys containing high hardness low toughness silicide compounds, taking advantage of the in-situ synthesis of alloys during the processing of multilayers. The PTA-DED technique is explored to process Niobium alloy multilayers aiming to assess the impact of elemental powder mixture complexities on the in-situ synthesis, solidification paths, metallurgical stability to multiple thermal cycles of additive processing and the oxidation resistance. Progressive additions of 5at%Al, 5at%Cr and 2at%Mo were made to an elemental powder mixture with a composition of Nb24Ti18Si+1Zr (at%). Results show that the presence of Al and Cr, individually or together, induces more segregation during solidification, leading to the formation of anomalous and ternary eutectics. However, the addition of Mo to the powder mixture stabilizes the high temperature primary phases and mitigates the solidification of anomalous eutectic. Multiple thermal cycles lead to a decrease in thermal gradient, resulting in coarse microstructures with overgrown silicides. It is shown that oxidation performance is determined by the presence and extent of the solid solution in the microstructure.

Thermodynamic and properties investigation of Cu modified niobium silicides diffusion coatings

Beatriz Aparecida Pinto[1], Ana Sofia Clímaco Monteiro D' Oliveira[2], Nabil Chaia[3]

[1]Universidade Federal do Paraná (*Departamento de Engenharia Mecânica*) , [2]Universidade Federal do Paraná (*Engenharia Mecânica*) , [3]Universidade Federal de Alfenas (*ICT*)

e-mail: beatriz.aparecida@ufpr.br

Niobium silicides coatings have been widely studied due to the combination of the silicides oxidation resistance and high-temperature creep resistance and relatively low density of niobium. To obtain more stable niobium silicide coatings with a double layer of silicides, NbSi2 and Nb5Si3, the literature presents the need for pack cementation processing at temperatures above 1200 ºC, increasing the cost of the process and making it difficult to control its variables. An alternative to this challenge would be to accelerate the synthesis of silicides by adding alloying elements that would enable the formation of the double layer of silicides at lower temperatures. In this research, the effect of adding Cu to the processing of niobium silicide coatings by pack cementation was investigated through thermodynamic and microstructural analysis. The processing was carried out with pack mixtures of Si with and without Cu at 1000 ºC for 6 hours. The HSC Chemistry software was used for thermodynamic analysis, and SEM, EDS, and nanohardness were used for coating analysis. Thermodynamic analysis shows that during processing, the formation of Si halides occurs mainly, and the Cu halides can be disregarded due to their low partial pressures. Deposition of only Si on Nb is confirmed by the formation of only Nb5Si3 and NbSi2 silicides in the coatings processed with pack mixture modified with Cu. Results show that coatings processed with only Si formed only the NbSi2 layer. In addition, coatings with Cu had thicknesses of 45.79 ± 2 μm, higher than coatings without Cu, which had 32.54 ± 2.38 μm. Coatings processed with Cu also showed a decrease in hardness (979 ± 65.33 HV) compared to those without Cu (1110.4 ± 45.34 HV). The results indicate that although Si and Cu do not co-deposit on Nb, the element impacts the formation and properties of silicide coatings, accelerating synthesis and possibly inducing more defects in the silicide structure, resulting in a decrease in their hardness.

The voids on high coercive Sm-Co films deposited on Ta buffer

Tainara Coutinho de Carvalho[1], Braulio Soares Archanjo[2,3], Renata Simao[4], Vitoria Barthem[5]

e-mail: tainara@coppe.ufrj.br

Besides the wide discussion of Ta as a buffer layer in the literature, an investigation into the influence of the transformation from β-Ta to α-Ta phases in heat-treated Sm-Co films remains unexplored. Here, the use of the Ta buffer and the capping layer on the Sm-Co thinfilms leads to an optimization of the magnetic properties. The hysteresis shows that, in thiscase, the Sm-Co films present high coercivity values, greater than 4 T, and a quadrature factor approximately equal to 1. The observed improvement in the performance of the Sm-Co films seems to be related to the concomitance between the crystallization process of theSm-Co films and the Ta transformation that occur during annealing. In particular, X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) results indicate theoccurrence of an intense diffusion process between layers, leading to the formation of thecrystallized $TaCo_3$phase. Additionally, transmission electron microscopy (TEM) analyzes show the presence of voids in the microstructure of the Sm-Co layer, which seem to act aspinning, providing the high values of coercivity observed. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Finance Code 001.

Advances in the investigation of kinetic parameters ofthe Al-V system

Vitória de Melo Silveira[1], Nabil Chaia[2], Carlos Angelo Nunes[1], Gilberto Carvalho Coelho[1]

[1]Escola de Engenharia de Lorena - EEL/USP, [2]Universidade Federal de Alfenas (*ICT*)

e-mail: vitoria.melo.silveira@usp.br

Vanadium alloys are investigated as cladding materials for nuclear fusion reactors, due to their low activation and good mechanical properties over a wide range of temperatures. However, the main problem of these alloys is that they exhibit a poor oxidation resistance at high temperatures [1], so they need external protection, as aluminide coatings. Also, it is vital to know the kinetic data of phases of the Al-V system, with the purpose of estimating the thermal stability of substrate/coating systems. The present work aims to determine kinetic parameters (growth constants and interdiffusion coefficients) in Al-V diffusion couples using an unconventional method, namely the pack cementation technique. Samples were cut from a pure V plate and arc-melted 66V-44Al (at. %) ingots. The aluminide coatings were produced using the halide-activated pack cementation (HAPC) technique. Assuming that diffusion in the gas phase is not a rate-limiting step, the coating formation can be understood as a classical semi-infinite diffusion couple. The samples were processed by the HAPC technique from 800 to 1000°C, for 4, 9, 16 and 25 hours. The coated substrates were microstructurally characterized by XRD, SEM and EDS. The solid state diffusion governs the growth of the coating layers, given that the thickness variations follow a parabolic law. The growth constants were obtained by linearizing the kinetic curves for each phase and they were used to calculate the interdiffusion coefficients, with the Wagner' s approach (1969) [2]. The kinetic parameters were calculated for the VAl_3, V_5Al_8 and (V) phases. The VAl_3 phase has interdiffusion coefficients approximately one to two orders of magnitude higher than the those of V_5Al_8 and (V).

The production of aluminum and its alloys is one of the most used in the metallurgical industry and with increasing use in aeronautics, automotive and shipbuilding. Because pure aluminum has little mechanical strength, other elements are added in alloy forms to meet the engineering applications, as is the case of alloy 6351, according to this understanding, for this work the alloy was subjected to thermal treatments, for the formation of a dense and fine dispersion of particles within the alloy to promote increased mechanical strength, and also a process of severe plastic deformation called ECAP (equal channel angular pressing) aiming to maximize the refinement in grain to promote the improvement of mechanical strength [1]. In this research the effect of ECAP on alloy 6351 samples subjected to heat treatments of solubilization, full annealing, and solubilization followed by aging will be analyzed. The process follows the introduction of each treated specimen into the die that consists of two channels of equal cross section that cross at an angle of 110°, and is extruded with the help of a punch. The processing temperature (150°C) and pressing speed (10mm/min) will be standardized [2], for later comparison, and the processing route (Bc) will be added. The microstructural analysis will be evaluated by optical microscopy (OM) and X-ray diffraction (XRD), and the mechanical properties by Vickers microhardness.

Analysis of the effect of simulated corrosion on the mechanical properties of biodegradable magnesiumalloy WE43

Geraldine Hincapie Diaz[1], Felipe Saconi[2], Marcelo Leite Ribeiro[2]

[1]Escola de Engenharia de São Carlos (USP) (*Engenharia mecanica*) , [2]Escola de Engenharia de São Carlos (USP)

e-mail: ghincapied@usp.br

Magnesium and its alloys are being considered to replace bioinert metallic materials in the fabrication of temporary trauma implants because they are biodegradable in the human body, making a second surgery for their removal unnecessary. However, a barrier to their implementation in orthopedic applications is the lack of knowledge about the effects of biodegradation on the structural integrity of this material. In this study, a numerical comparison of the mechanical properties of the WE43 magnesium alloy is carried out in order to predict the effects of localized and stress corrosion on its structural integrity and to differentiate the influence of this phenomenon. Therefore, the mechanical behavior of the alloy was simulated by means of a von Mises elastoplastic model, coupled to a continuous damage model of localized pitting corrosion and stress corrosion cracking, through the development of a subroutine (VUMAT) in the Abaqus®/Explicit software. Subsequently, this corrosion model is calibrated according to the data obtained from mechanical characterization and in vitro degradation tests. According to results, it is possible to note that both localized and stress corrosion models are able to capture the effects of reducing the fracture loss mass with increasing mechanical loading. Regarding the influence of stress corrosion on the mechanical properties of the material, the small difference in the mass loss at fracture value found between the two corrosion models suggests that the localized corrosion mechanism is the main influencing factor in reducing the structural integrity of the material caused by corrosion.

Analysis of the effects of normalization on gray castiron brake disc samples

Athus Igor Castro Holanda[1], Jullyane Raquel Almeida Nunes[1], Luana Borges Goularte[1], Lucas Yoshi Tsugawa Palheta[1], Amanda Lucena de Medeiros[1]

[1]Universidade Federal do Pará (*Faculdade de Engenharia Mecânica*)

e-mail: athusholanda07@gmail.com

Gray cast iron is a ternary alloy of Fe-C-Si with percentages above 2% carbon, its properties, such as high degree of hardness, wear resistance, vibration damping, indispensable given wide use, being one of the metals consumed in large scale for production of products, mainly in the secondary sector (metal manufacturing), especially for the automotive industry. The objective of this work is to perform comparative analysis of the microstructure of the part and the hardness obtained aiming to find arguments to corroborate the claim that the sample of a standard brake disc has been manufactured from gray cast iron. The comparison method of visual analysis of the samples will be used (raw and treated) via images from researched literature, as well as explaining the steps, from cooling in still air outside the furnace (muffle type), followed by grinding (sandpaper from 80 to 1500), polishing (alumina of 0. 05, 0.3 and 1 micrometer alumina), chemical attack with 3% nital reagent (with time around 15 seconds of attack), and even obtaining data for the Rockwell C hardness test. In summary, it is concluded that, normalization is not usual in the manufacture of brake discs, due to the reduction of hardness, which is primordial to the mechanical property of wear resistance.

Analysis of the metallurgical effects of bismuth addition on the machinability of the alloy Al-12.6wt.% Si: temperature and cutting tool wear criteria

Fernando Sousa da Rocha[1], Fabrícia Sousa Gonzaga[2], Alexandre Augusto Baldez Gatinho[2], André Cruz da Costa Maciel[2], Maria Adrina Paixão da Silva[2], Thiago Antônio Paixão de Souza Costa[3], Otávio Fernandes Lima da Rocha[3,2], Antonio Luciano Seabra Moreira[2]

e-mail: nandosrocha12@hotmail.com

Al-Si alloys are widely used in industry to manufacture components that are exposed to critical wear conditions, as they provide better mechanical properties and higher resistance to corrosion and defect propagation [1]. Machining is one of the most widely used manufacturing processes in industries, however Al-Si alloys are characteristic to present low machinability, especially those with more than 12.0wt% of solute content, because of the great tendency of these alloys in adhering on the cutting tools [2]. This is a motivation factor to the development of research that investigate the effect of alloying elements, such as bismuth, to improve the machinability of the Al-Si system and that can predict microstructural conditions and solidification parameters that facilitate the machinability of these materials. Thus, an experimental study was conducted with Al-12.6wt.%Si and Al-12.6wt.%Si-3.2wt.%Bi alloys solidified in a water-cooled vertical directional device to establish correlations between microstructure and average cutting temperature during necking processes on a bench lathe. From the experimental results, a power-type function was obtained, which relates the cutting temperature according to the eutectic spacings, from the base to the top of the ingot, and was observed that the cutting temperature decreased with increasing eutectic spacings. Besides, the results show that the addition of 3.2wt.% of bismuth in the Al-12.6wt.%Si alloy increased the cutting temperature, however decreased the wear of the cutting tool, which remained constant for the samples analyzed.

The present work consists in a case of study focused on the analysis of civil construction waste, resulting from the construction of a single-family residence in the city of Teresina-PI. The study begins with a bibliographic review, where multiple concepts about civil construction waste are presented, aiming to improve the understanding of the term for a better experience in this work. Subsequently, methodologies are presented not only to classify the waste found, but also to prevent, mitigate and combat all types of losses. The analysis of the residential waste object of this paper starts from the earthworks until shortly before the stage of completion, passing through the planning, foundation, installations, roofing and another phases. The research showed that, even with the advancement of technologies to combat civil construction waste, a more rigorous control and a better awareness of the need to implement practices aimed at reducing losses in works in search of improvements for the environment, the company and the consumer, are still required, and the practices to combat waste presented in this work are an excellent way to initiate this change.

Analytical techniques to study the contamination byheavy metals on the beaches of Sepetiba Bay

Flaviane Roque Oliveira da Silva[1], Daphne Dias da Silva[1], Gabrielle Laut Lopes Marinho[1], Rodolfo Salazar Peres[1], Ana Isabel de Carvalho Santana[1], Roberta Gaidzinski[1], Neyda de la Caridad Om Tapanes[1]

e-mail: flavianeroque@gmail.com

The Sepetiba Bay occupies an area with great natural resources and high viability for undertakings related to the processing and transport of ores. Given this scenario, since 1950, investments in the mining sector have been increasing. Nowadays, there are more than 100 companies in the sector that generate ores and residual metals, leading to devastating environmental consequences in the hydrographic basin, such as the reduction of the Atlantic Forest, water contamination, severe reduction of fishing area, contamination of fauna and flora [1]. In this context and with the objective of evaluating the current advance of contamination in the region, the present research analyzed the content of metals in the sands of the beaches belonging to the three cities that border the Bay: Itaguaí, Mangaratibaand Rio de Janeiro. Through a factorial design of experiments, 9 beaches and two sources of contamination were selected. Two quantitative factors were evaluated: distances between the beach and each source of contamination and a qualitative factor (season: summer or winter). The response variable was the metal content determined using the x-ray diffraction (XRD) and x-ray fluorescence (FRX). The ANOVA and the response surface methodology were used to statistically evaluate the degree of soil contamination. A second-order regression model showed the statistical significance of contamination focus 2 and the influence of the season. This last result corroborates published studies on the low rate of water renewal during the summer months [2]. The results obtained allowed identifying the degree of contamination increase to establish a possible recovery plan.

e-mail: danielle_camilo@yahoo.com.br

In recent years, heterogeneous materials have been emerged as a new way to optimize properties taking advantage of mechanical behavior of two or more alloys in one bulk sheet [1]. The Accumulative Roll- Bonding (ARB) is a suitable process for heterostructured sheets production, since it achieves mechanical bonding between dissimilar metals or alloys [2]. In this work, heterostructured sheets were produced using two Al alloys: the age-hardenable AA7050 alloy and the highly ductile AA1050 alloy. The former has been extensively investigated in order to achieve a good combination between high specific strength and corrosion resistance [3]. However, the existing research is insufficient to stablish a correlation between heterostructures and corrosion properties, and thus stress corrosion cracking (SCC) sensitivity of these materials has far less been investigated. Firstly, sheets of both alloys in the annealed condition were stacked and then rolled with a thickness reduction of 50% in a single pass at 450 °C or 500 °C. The roll-bonded sheets were wire-brushed, cleaned, cut and stacked, pre-heated for 5 minutes at the process temperature and the procedure was repeated up to eight times. Therefore, the effect of processing parameters (number of cycles and temperature) on the SCC sensitivity using slow strain rate (SSR) tensile tests in a 3.5 wt.% NaCl aqueous solution were examined. Microstructure evolution, tensile behavior and fracture surface analysis were discussed to address the combined effects on the SCC sensitivity.

AISI 304 steel is an austenitic stainless steel used in various applications, such as equipment for chemical, petrochemical, and food industries, biomedical prostheses, mechanical construction, among others [1,2]. Thin films were deposited on AISI 304 stainless steel substrates using different plasma-based PVD (Physical Vapor Deposition) techniques, namely duplex, simultaneous duplex, and deposition, using a Ti cathodic cage. The objective was to evaluate the influence of the applied technique on the mechanical and tribological properties of the films. The samples were analyzed using X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM) characterization techniques, as well as Vickers microhardness, Rockwell C adhesion and wear resistance tests. The results showed an increase in surface microhardness for all films obtained, with good adhesion characteristics, especially for the samples from the duplex and simultaneous duplex treatments. The simultaneous duplex treatment sample exhibited the best wear resistance results when compared to the other treated samples and the untreated substrate, highlighting the efficiency of this technique in obtaining films with good mechanical and tribological properties obtained in shorter treatment times than conventional duplex treatment.

From both a metallurgical and economic stand point, it is extremely interesting to understand the influence of temperature on the oxidation rate of distinct steel alloys, since, depending on composition and temperature different oxidation mechanism can be identify [1]. This is specifically important during hot working of steel where the oxidation products are undesirable and their formation should be minimized to reduce production cost [2]. In this work two mechanical construction steel were studied at temperatures ranging from 900°C to 1200°C. The kinetic parameters were obtained from high temperature oxidation tests carried out in an unsealed PID-controlled oven for 0,5 h to 4 h. The samples masses were measured prior and after the experiment and the difference was used to calculate the overall gain of mass. The results have shown that the kinetics parameters of the AISI 1045 and 4340 alloys, are very similar, 104.449 J.mol-1, and 98.937 J.mol-1, respectively, both following a parabolic oxidation mechanism. Nevertheless, since the oxidation rates of both alloys were lower than that that of pure iron [3], carbon content and other alloying elements may have hindered oxides formation. Besides, the SEM/EDS analyses revealed a very porous oxide layer containing a carbon gradient decreasing from the metal-oxide to the oxide-air interfaces, suggesting carbon diffusion from the metal to the oxide, followed by its oxidation to CO2 in the presence of atmospheric O2.

Measuring the volume of an atom is a complex task due to its dependence on multiple factors, such as the number of electrons in the atom, the type of bond it forms, and its nearest neighbors, etc. As a result, accurately measuring the atomic volume is not always possible. In this work, we present a functional methodology for measuring the Apparent Atomic Volume (AAV), which is the volume occupied by the atoms in a unit cell. To determine the AAV, we utilized Density Functional Theory (DFT) calculations and X-ray diffraction analysis with a synchrotron source. We examined pure Ni, as well as single-phase FCC systems of NiPd, NiV, CrCoNi, CrConiV, and CrCoNiPd alloys. The DFT results demonstrated a strong correlation with our XRD findings and were consistent with previously published experimental data. Moreover, the methodology enables to obtain functional measurements that can be used to correlate with the mechanical properties of metals and their alloys. This approach can be a valuable tool in enhancing the intelligent design of alloys and more precise control over their properties. e-mail: slavson@iff.edu.br

The search for new materials involves a great effort in evaluating their properties. One such property of interest is the electrical property. This work presents the SAME, an automatic electrical measurement system, whose operating principle is the Acquisition, Storage, and Treatment of Electrical Resistance Measurements of materials versus temperature variation. The electrical characterization involves knowing the behavior of its electrical resistance related to temperature. For thin films, this temperature range of interest extends from room temperature to about 700°C in several cycles, which imposes a very high dedication time by researchers. The system produced in the thin film laboratory at LAMAV/UENF integrates a temperature control system of a rudimentary oven, a bench multimeter for acquiring resistance measurements and a microcomputer connected to the multimeter to record and process the data obtained. All man-machine interaction is done from the computer in a program written in Python, the graphical SAME, which presents an interface where the operator must configure the temperature parameters, number of cycles and desired time for stabilization. A second application, the statistical SAME, performs the statistical treatment of the measurements obtained and issues the report with graphs representing the behavior of the electrical resistance of the material versus temperature. The average time to carry out the electrical characterization of a sample was 1415 minutes of manual availability by the researcher and, with the implementation of SAME, this time was reduced to 5 minutes, which is the average time spent setting up the experiment. Thus, the SAME was satisfactory in terms of the results obtained in relation to the repeatability of the tests and the convenience of the users.

CHARACTERIZATION OF A 2205 DUPLEX STEEL MODIFIED WITH BORON OBTAINED VIA POWDER METALLURGY

Pedro Morita Terceiro[1], Juliano Soyama[2]

[1]Universidade Estadual de Campinas (*Materiais e Processos de Fabricação*) , [2]Universidade Estadual de Campinas

e-mail: p223451@dac.unicamp.br

Stainless steels are commonly used when a good balance between mechanical properties and corrosion resistance is required [1]. However, depending on application conditions, they may have low wear resistance. Usually, to increase wear resistance, hard particles are added (carbides, borides, nitrides and others.) to the more ductile matrix (ferrite or austenite). As the addition of boron leads to the formation of primary and eutectic borides,which harden the material as solidified. [2] Traditional techniques such as casting and machining are difficult to apply. Therefore, this work will investigate the viability to preparea modified 2205 duplex steel with 2.5% wt. of boron through powder metallurgy. This technique is an alternative way to process materials that are normally difficult to form bytraditional methods. Consequently, this study involves investigate the influence of temperature on sintering process, as well as the study of microstructure formation, thermaland mechanical properties. The samples were prepared from a pre-alloyed metal powder bycold uniaxial compaction and sintered in a controlled atmosphere.

e-mail: mariani.fabioe@gmail.com

Ni-based alloys are used for a wide variety of applications, with the majority of them being involved in corrosion resistance and/or heat resistance. These applications include aircraft turbines, heat-treating equipment, and the chemical and petrochemical industries. The addition of high-hardness carbides to these alloys can increase their wear resistance, thus expanding their range of use. In this study, mixtures of powdered nickel alloy (used as the matrix bonding material) and titanium carbides (used as the hardening ceramic phase) were utilized to produce metal-matrix composites (MMC) layers with the aim of achieving superior tribological performance. Nickel-based powder, combined with 20%, 40%, and 60% TiC agglomerated with an organic binder, was deposited as a slurry onto samples of AISI 1020 steel. Subsequently, the coatings were melted using the laser alloying process. The layers and substrate were characterized through optical microscopy, Vickers microhardness, and micro-adhesive wear tests. All coatings outperformed the substrate in terms of hardness and wear resistance. TiC additions above 40% led to the agglomeration of carbides.

Characterization of the parameters of the stress-strain curve in high nitrogen austenitic stainless steels

João Marcos da Silva Nunes[1], Eden Santos Silva[1], Samuel Filgueiras Rodrigues[2], Gedeon Silva Reis[1], Jéssica Bezerra Serra[1]

[1]Instituto Federal de Educação, Ciência e Tecnologia do Maranhão (*Programa de Pós- Graduação em Engenharia de Materiais*) , [2]Instituto Federal de Educação, Ciência e Tecnologiado Maranhão

e-mail: nunesjoao@acad.ifma.edu.br

High-nitrogen austenitic stainless steels have been used in the manufacturing of orthopedic implants subjected to severe loads over long periods of time due to their excellent mechanical properties, good biocompatibility, and affordable cost compared to titanium alloys. However, research indicates that the percentages of Ni, N, and Nb have been harmful to the human body and pose challenges to the production and processing of the alloy, resulting in structural, microstructural, and mechanical defects. [1,2] Physical simulation of thermomechanical processing allows for estimating the dependence of thermomechanical processing parameters on the mechanical-microstructural responses of the alloy under conditions similar to industrial settings.[3] In this research, the competition between dynamic recovery and dynamic recrystallization is characterized through constitutive analysis of stress-strain curves obtained from continuous isothermal hot torsion tests at different temperatures (900-1200 °C) and deformation rates (0.01-10s^{-1}), along withan estimation of dislocation density along the plastic flow curve. The results show that the activation energy for hot deformation (Q_{def} = 594 kJ/mol) is high compared to the class of austenitic steels, delaying the mechanisms of dynamic softening (DRV-DRX) and being significantly affected by the moderate value of the stacking fault energy ($\gamma_{SFE} \sim 68.7$ mJ/m^2) and fine precipitates of the Z phase (CrNbN) present at grain boundaries, which shape the stress-strain curves.

Characterization of Waste from Sustainable Hydrogen Generation via Metal-based Pathways

Beatriz Jacob Furlan[1], Paulo Alexandre Silveira da Silva[2], Lauber de Souza Martins[3], Lúcio Cardozo Filho[4], José Viriato Coelho Vargas[2]

[1]Universidade Federal do Paraná (*Engenharia e Ciência dos Materiais*) , [2]Universidade Federal do Paraná (*Engenharia Mecânica*) , [3]AdventHealth University, [4]Universidade Estadual de Maringá (*Engenharia Química*)

e-mail: beatrizfurlan@ufpr.br

The high global demand for energy has led to the search for a sustainable energy matrix. The hydrogen-based economy has emerged as a possible solution to the energy problem, as hydrogen is the known fuel with the highest calorific value in mass basis and is the simplest and most abundant gaseous element in the universe [1]. Its generation can be obtained by metallic ways, e.g. the oxidation of aluminum in alkaline solution, hereupon the use of recyclable metals is an option for sustainable hydrogen production processes [2]. However, as in any chemical reaction, the generation of hydrogen can result in wastes, being crucial to characterize them in order to understand their properties, evaluate their reuse and proper disposal. Thus, the waste generated was subjected to three characterization techniques: Scanning Electron Microscopy (SEM), Atomic Force Microscopy (AFM) and Thermogravimetric Analysis (TGA). SEM provides high-resolution images of the morphology and structure of the surface of the waste, enabling detailed information to be obtained about shape, size, particle distribution and surface roughness. AFM analyzes topography and surface mechanical properties at the nanometer scale, including 3D measurements and information on hardness, elasticity and adhesion. While the TGA allows analyzing the thermal behavior of the waste, including changes in mass, presence of water, decomposition of compounds, thermal stability of the material and determination of purity. Thereby, looking at sustainable hydrogen generation as a promising prospect for technological advancement and energy migration, it is essential to fully understand the hydrogen generation reaction and characterize the obtained product in order to establish a sustainable process chain.

The economic development of nations is related to how they use their sources of energy. In 2016, the consumption of energy in the industrial refrigeration sector was 51% of final energy use1. Traditional refrigeration systems use refrigerators such as water, air, hydrocarbons, ethylene glycol, etc. A viable alternative that aims to improve the properties of fluids is adding nanowires (NW) dispersion in those fluids, getting a colloidal sol called nanofluid (NF)2. CuNW's were chosen because of the lower cost of the metal, the abundance of it and the good conductivity when compared with silver nanowires3. The present work aims to obtain NWs produced from the synthesis and modification of copper functionalized with polyvinylpyrrolidone using an electric pressure cooker. These materials were obtained by the chemical reduction method. The obtained samples were characterized by XRD to identify the crystalline phases and FTIR spectroscopy to assign chemical composition to the samples. The formation of the CuNW material is dependent of the type and time of stirring, which were possible to obtain with 12 hours of vigorous stirring. With the FTIR spectra, it was possible to identify PVP coating the NW's, however with some features of oleilamine (OE) and oleic acid (OA) in the surface. Future studies are necessary to understand the effects of OE and OA in the CuNW materials.

Correlation between interfacial heat transfer coefficient, primary dendritic arm spacings, andmicrohardness in the horizontally solidified Al-11wt.%Si alloy

It is important to know the variation of dendrite arm spacings during the solidification process to analyze microsegregation pattern which influences the homogenization kinetics, ultimate tensile strength, ductility, toughness and yield tensile strength of solidified alloys [1]-[3]. The main purpose of this work is to present a theoretical-experimental study for the prediction of the interfacial heat transfer coefficient during the horizontal directional solidification of an Al-11wt.%Si alloy on water-cooled stainless-steel chill under transient heat flow conditions. Six thermocouples were connected with the casting and the time-temperature data were recorded automatically. A numerical technique which compares theoretical and experimental thermal profiles was used to measure the heat transfer coefficient values. This has permitted the evaluation of the variation of this thermal parameter along the solidification which is represented by a power equation that shows the time dependence during the process given by h_i=constant$(t)^{(-n)}$, representing the best fit between the experimental and calculated curves. The obtained results also include the variation of primary dendritic arm spacings of alloy analyzed as a function of interfacial heat transfer coefficient. These dendrite arm spacings were found to decrease as the values of this coefficient are increased. Finally, an experimental law of the Hall-Petch type is proposed relating the resulting microhardness to the heat transfer coefficient investigated.

e-mail: rmlobo@ipen.br

The Small Punch Test (SPT) was development by nuclear industries to analyses mechanical properties of irradiated materials principally by small volume of the samples. This technique intend to evaluate the materials behavior during the time life of nuclear reactors, where yours properties changed by irradiation intensity and exposition time. It is considered an almost ¨non-destructive” method [2] due to small sample volume and its applications are spreading for use in situations where conventional methods do not apply. SPT consists of pressing a sphere, with a diameter equal to 2.5 mm, in a miniaturized sample of circular geometry (diameter d = 8 mm and thickness about 0.5 mm)[1], which has fixed edges, tested in conventional mechanical testing machines with the aid of a device developed for their achievement. In this work, mechanical properties of aluminum (Al 6061-T6) were abstained by two different methods: conventional tensile test and the small punch test (SPT). The SPT results depends on graph interpretations and discussions take place at now. Correlations of results guide us in choosing the most appropriated method for interpreting the force x displacement graph from SPT.Acknowledgements: We thank Dr. Arnaldo H. P. Andrade for his invaluable collaboration (in memoriam)References:[1] ASTM E3205-20 Standard Test Method for Small Punch Testing of Metallic Materials, Annual Book of ASTM Standards, Part 03.01, ASTM International, 2020[2] M. e-mail: thassiafelix@usp.br

Aluminum Alloy (AA) 2024-T3 is a high-strength heat-treatable alloy used in aircraft design as structural and skinning material for the fuselage, due to the combination of good mechanical properties and light weight. The thermomechanical processing of the alloy increases its mechanical resistance; however, it also generates a complex and heterogeneous microstructure susceptible to localized corrosion. Traditionally, protection of aerospace AA is performed in Cr(VI) containing anodizing and post-treatment solutions. However, environmental concerns and stricter legislation on the use of such chemicals require the development of low-cost and environmentally friendly processes. As an alternative, tartaric-sulfuric acid (TSA) anodizing has been proposed. It is reported that the addition of corrosion inhibitors to the anodizing bath and/or their use in a post-treatment step can improve the anticorrosive properties of the anodic layer. We investigated the effects of adding molybdate ions to the TSA bath followed by post-treatment in a Ce containing solution on the corrosion resistance of AA2024-T3. The investigation was carried out by combining characterization (RBS, TEM and SEM-EDS) with electrochemical (EIS) techniques. RBS and TEM indicated the incorporation of Mo and Ce ions in the anodized layer; while the SEM analysis showed that a thicker oxide layer was obtained for the samples anodized in the Mo-TSA bath when compared to the TSA bath and that the post-treatment with Ce reduces the thickness of the layer. The EIS analysis in 0.1 mol.L-1 NaCl revealed improved corrosion resistance for the samples with Mo and Ce io while fitting of the EIS diagrams with electrical equivalent circuits showed that the inhibitors improved the protective properties of the oxide layer without modifying the protection mechanism.

Design and characterization of lightweight steels reinforced by TiB_2

André Luiz Vidilli[1], Lucas Barcelos Otani[1], Vicente Amigó Borrás[2], Claudemiro Bolfarini[1]

[1]Federal University of Sao Carlos (*Engenharia de Materiais*) , [2]Instituto de Tecnología de Materiales

e-mail: andre.vidilli@gmail.com

The lightweight steels of the FeMnAlC system were developed due to the automotive industry''s demand for materials with greater specific strength [1]. Belongs to the class of Advanced High-Strength Steels (AHSS), FeMnAlC steels have a high capacity to store dislocations which results in a high work-hardening rate and delay in the onset of plastic instability. Consequently, these steels exhibit an outstanding combination of strength and ductility [2]. Compared with the conventional steels, the lower density is mainly obtained by aluminum additions, which, together with the lower atomic mass, is responsible for the increase in the lattice parameter. However, aluminum also reduces the steel''s stiffness, limiting potential applications. In this context, the introduction of ceramic particles in the FeMnAlC matrix is an interesting strategy to minimize the negative effects associated with the Al, increasing the stiffness and further decreasing the density. The present work tailored FeMnAlC steels reinforced by TiB_2particles formed by in-situ reaction. The compositions were designed by thermodynamic calculations and the composites were processed by arc-melting and spray-forming routes. It was evaluated the microstructure, physics and mechanical properties.

Design of Thermally Stable Microstructure After Equal Channel Angular Pressing at Cryogenic Temperatures

Pedro Henrique Fernandes Oliveira[1], Diogo Pedrino Braga[2], Danielle Cristina Camilo Magalhães[3], Osvaldo Mitsuyuki Cintho[4], Andrea Madeira Kliauga[3], Vitor Luiz Sordi[3]

[1]Universidade Federal de São Carlos (*Engenharia de Materiais*) , [2]Universidade Federal de São Carlos (*Departamento de Engenharia de Materiais*) , [3]Univerdade Federal de São Carlos (*Engenharia de Materiais*) , [4]Universidade Estadual de Ponta Grossa (*DEMA*)

e-mail: pedrofholiveira@hotmail.com

Equal Channel Angular Pressing (ECAP) at cryogenic temperatures has been adopted to increase the strain severity by suppressing dynamic recovery and accumulating crystalline defects. However, severely deformed microstructures at cryogenic temperatures have limited use due to the microstructural instability presented, a consequence of the high internal energy stored as crystalline defects (vacancies and dislocations). In fact, some studies observed an evident grain growth after cryogenic processing when these materials were stored at room temperature. In this sense, this work aimed to design microstructures that are long-term stable after processing at cryogenic temperatures. The adopted strategy was to introduce a fine dispersion of precipitates in a severely deformed microstructure, to anchor the movement of dislocations and/or high and low angle contours. As a consequence, thermally activated phenomena, i.e., recovery and recrystallization would have their kinetics significantly reduced. Hence, the present work investigated the thermal and microstructural stability Cu-0.7Cr-0.07Zr alloy after processing by ECAP at cryogenic temperature, comparing it with electrolytic copper processed under the same conditions. After ECAP processing, the Cu-0.7Cr-0.07Zr alloy was subjected to aging treatment. The results showed that, after cryogenic processing, pure copper was microstructurally unstable, even when stored at room temperature, while the precipitates formed during aging were effective in stabilizing the microstructure of the Cu-0.7Cr-0.07Zr alloy.

The authors would like to express their gratitude to Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES - process nº 88882.332697/2010-01)

Development of a new reagent for the reveling of theprior austenite grain boundaries of AISI D2 steel.

EDUARDO JOSÉ BERNARDES[1], Paula Fernanda da Silva Farina[1]

[1]Universidade Estadual de Campinas

e-mail: eduardojbernardes@gmail.com

For the steels'' microstructure characterization, it is necessary to use a revealing solution. Previous research has shown that the reagents currently used to reveal the grain boundary also attack the interior of the grains, resulting in stains, and pitting corrosion, which makes it difficult to use an image analysis program to quantify them. The objective of the current work was to develop a reagent capable of revealing only the grain boundaries. Through the formulation of solutions based on Vilella''s reagent, it was possible to obtain a solution capable of exclusively revealing the primary austenitic grain contour without the use of a high-temperature chemical etching, thus allowing a better quality in the outline of the contours. The analyzed steel was AISI D2 steel, and from sanding, polishing, and subsequent chemical etching with the developed solution, it was possible to outline only the grain contour without generating pits of corrosion, or stains, with no need to use an image editing program to analyze the average diameter of primary austenitic grains.

Acknowledgment

e-mail: jrvfisica@gmail.com

The theoretical studies of coordination complexes were improved with the implementation of density functional theory (DFT) methods. Reliable DFT functionals to study coordination complexes have been developed [1]. The objective of this work was to investigate the geometrical, electronic, and energetic properties of a Mn(II) coordination complex with 1,10-phenanthroline and maleate ligands using the DFT and to study the main intermolecular interactions in the crystal lattice of the complex through Hirshfeld surfaces (HS) analyses. DFT calculations were performed with the Gaussian 16 software, using the PBE1PBE functional and the 6-311++G(d,p) basis set for H, O, C, and N atoms, employing the SDD pseudopotential and basis set for the Mn atom. HS analyses were performed using the CrystalExplorer software [2], starting from data available in a crystallographic database [3]. From the optimized geometry obtained from the DFT calculations, we observe that the complex has a distorted octahedral structure. The values of Gibbs free energy and enthalpy of the complexation are negative, indicating that the formation of the complex is spontaneous and exothermic. The HOMO and LUMO have been plotted and the energy gap between α-HOMO (the true HOMO) and β-LUMO is 4.19 eV, which was used for the calculation of reactivity indices. HS analyses indicated that H···H and H···O interactions arethe most significant, contributing with 36.5% and 35.3% of the intermolecular interactionsin the crystal, respectively. In this way, this study showed that the formation of the coordination complex is favorable and revealed the main interactions contributing to the stability of the crystal.

e-mail: murilo@aluno.ufrb.edu.br

The demand for more sustainable alternative sources of energy production is growing all over the world. In this context, wind energy proves to be a valuable clean energy source to diversify the global energy matrix. Wind turbines are devices that convert the wind kinetic energy into electrical energy, with their main components being the blades and gearbox. The blades, fixed to the rotor, are responsible for capturing the wind and transmitting itspower to the rotor shaft, which then transfers the slow movement to the gearbox. Thegearbox transforms this rotation into a higher speed, which is responsible for generatingenergy in the stator. Soon, the gearbox is a critical part of this system and it is subject tocontinuous wear due to friction between metallic components. The wear of gears and bearings can lead to early equipment failure, increased maintenance costs, and productionbreakdown. In this context, the application of DLC coatings appears as a viable solution tomitigate it. In this study, DLC coatings are proposed for deposition on the steels surface toreduce the coefficient of friction and increase the resistance of the material. DLC will beevaluated in terms of their quality and stress state through Raman Spectroscopy. Additionally, the adhesion of the DLC to the steel substrate will be assessed usingscratching and Rockwell C tests. The morphology of the DLC coatings will be examinedusing a Scanning Electron Microscope. Moreover, the hardness of the DLC coatings will bedetermined by conducting nanohardness tests, while the wear resistance will be evaluatedthrough a tribometer test involving a spherical tip. DLC has high hardness, is chemicallyinert, resistant to wear, and reduces the surface roughness of steel. These DLC unique properties can provide the gearbox with less internal friction and greater durability contributing to increased wind turbine productivity.

EFFECT OF AGING AND COLD FORMING OF THE ALUMINUM ALLOY (AA6351)

Thiago Figueiredo Azevedo[1], Carla Alessandra da Silva Correia[2], Weslley Rick Viana Sampaio[3,4]

[1]Instituto Federal de Educação, Ciência e Tecnologia de Alagoas (*mecânica*) , [2]Instituto Federal de Educação, Ciência e Tecnologia de Alagoas (*Mecânica*) , [3]Instituto Federal de Educação, Ciência e Tecnologia do Maranhão, [4]Universidade Federal de Alagoas

e-mail: thiago.azevedo@ifal.edu.br

Aluminum alloys are versatile enough for its lightness, ductility and toughness when compared to steels. The handling of some alloying elements intentionally added in Al alloys gives great improvement in mechanical properties, ductility and toughness. Heat treatments when applied in optimum conditions make the alloys with even more efficient properties. With the solubilization followed by aging, we can achieve a considerable increase in resistance. The objective of this study was to determine the shortest time of aging with 100% cold forming and 0% cold forming in the AA6351 alloy. It was observed that no 0% cold forming samples showed an increase in microhardness when aged up to 150 min, while 100% the cold forming samples there were no significant differences up to 180 min. The microstructure of these conditions showed that the 0% cold forming samples did not present visible microstructural change, while in 100% cold forming samples there were the presence of deformation bands.

Effect of aluminum alloying on the structure and properties of TiNiCuNb shape memory alloy

Mariana Lumi Ichihara Sado[1], Jéssica Dornelas Silva[2], Dilson Silva dos Santos[1]

e-mail: marianalumi10@gmail.com

The microstructure, mechanical behavior and martensitic transformation (MT) were evaluated in regard to the effect of low Al (x=0, 0.5 and 1 at.%) content on the Ti48Ni38Cu(10-x)Nb4Alx (at.%) shape memory alloy (SMA). As cast alloys were subjectedto the X-ray diffraction (XRD) technique to analyze phase constituents and cristallinity; scanning electron microscope (SEM) to discover secondary phase particles sizes, morphology, homogeneity and distribution along the structure, and energy-dispersive X-ray spectroscopy (EDS) mapping to study the distribution of the chemical elements. The MT critical temperatures and enthalpy changes were determined by differencial scanning calorimeter (DSC). Furthermore, hardness measurements were used to evaluate the microstructure influence in the mechanical properties. Experimental results show that the increase of Al content is capable of successfully enhance microstructure refinement and homogeneity as observed by MEV and reduce MT temperatures. This newly developed alloy contributes to the development of SMAs with optimized microstructure for new applications, such as solid-state refrigeration systems.

Al-Si alloys are increasingly being employed in the aerospace industry, satellite bearings, and inertial navigation systems [1]. However, the inherent fragile nature of Si crystals represents a limitation to the development of new applications in automotive and aerospace industries, which requires good ductility [1]. It is well known that bismuth (Bi), as an alloying element, is widely used to refine the microstructure of aluminum alloys as the Al-Si alloy system [1,2]. In this sense, the main purpose of this work is to carry out an experimental study on the effect of bismuth addition on the growth rates (G_R), cooling rates (C_R), Halo-like dendrite tertiary spacing (λ_3) and Rockwell hardness F (HRF) of the Al-12.6wt.%Si eutectic alloy. To evaluate the effect of both G_R and C_R on dendritic microstructure, optical microscopy techniques and Image J software were used to measure the λ_3 values at positions from the heat transfer surface of a water-cooled directional solidification device. The mathematical expressions, given by the general equations $\lambda_3 = \text{Constant}(G_R)^{-1/4}$ and $\lambda_3 = \text{Constant}(C_R)^{-1/4}$ characterized the λ_3 variations as a function of the respective solidification thermal parameters. It was found that the addition of bismuth decreased the HRF and λ_3 values. It was also observed that the cooling system imposed a decreasing profile of λ3 values from the bottom to the top of the molten ingot as well as the HRF results decreased with increasing λ_3 for both alloys. A comparative analysis was also carried out with literature values.

Effect of Cu additions on the wear behavior of AISI 316L single-walls manufactured by Plasma TransferredArc

Gustavo Scheid Prass[1,2], Ana Sofia Clímaco Monteiro D' Oliveira[3] [1]Universidade Federal do Paraná, [2]Instituto Senai de Inovação em Processamento a Laser,
[3]Universidade Federal do Paraná (*Engenharia Mecânica*)

e-mail: gustavo.prass@sc.senai.br

Modification of austenitic stainless steels with Cu induces a range of changes from thermal conductivity to biological resistance. This investigation further contributes to this discussion as it addresses the impact of Cu on the wear resistance of AISI 316L. Cu was added to the atomized stainless steel as microparticles (MPs) and as nanoparticles (NPs). Cu nanoparticles (NPs) have been used to enhance the properties of bulk materials due to their high surface-to-volume ratio [1, 2]. The impact of the NPs depends on the processing technique that will determine their distribution on the microstructure and hence on the properties. In this study, plasma transferred arc (PTA) was used to fabricate AISI 316L single-walls with and without Cu. 1 and 5 wt% Cu microparticles (MPs), 1 wt% Cu NPs and1 wt% CuO NPs were individually added to the gas-atomized stainless steel. Deposited single walls were subjected to solubilization at 1100 ºC for 0.5 h followed by air quenching. Aging treatment was carried out at 700 ºC for 0.33, 1.0 and 3 h. As built and heat-treated microstructures were assessed by optical microscopy and hardness measurements. 100Cr6 ball-on-disk wear tests were performed at room temperature under an applied force of 5.0 N, rotation of 125 rpm and 2500 laps. Wear tracks were evaluated by confocal microscopy and scanning electron microscopy (SEM). The hardening effect due to Cu precipitation was observed in all samples containing Cu, whereby longer aging times led to higher hardness. Samples containing CuO NPs showed the highest hardness in all heat-treated conditions. Regardless of the heat treatment applied, a higher Cu content led to a slightly lower coefficient of friction (COF) which resulted in a significant reduction in sample wear rate (SWR). The presence of NPs had no significant impact on COF or on SWR.

The study of the addition of molybdenium by electrodeposition in alloys containing less noble metals such as iron can improve their mechanical properties and corrosion resistance [1]. In addition to the addition of iron, other elements such as phosphorus can improve the mechanical properties and corrosion resistance of iron and molybdenum-based alloys [2]. Thus, the objective of this work was obtain the Fe-Mo-P alloy from the electrodeposition process and characterize the properties of the coatings. An electrolytic bath composed of sodium citrate (0.50 M), iron sulfate (0.03 M), sodium molybdate (0.09 M) and sodium hypophosphite (0.09 M) was developed. The parameter evaluated in the deposition process was the current density (30 mA/cm2 and 60 mA/cm2), at pH 6. The chemical composition was evaluated by EDX, the microstructure by XRD and the surface morphology by SEM. The corrosion resistance of the coatings was evaluated using the Potentiodynamic Polarization (PP) technique, in a saline medium (NaCl, 3.5%). The EDX results confirmed the formation of the Fe-Mo-P alloy following the induced co-deposition mechanism [3]. SEM results showed the presence of microcracks and the formation of superficial nodules. The XRDresults confirmed the amorphous character of the coatings. The corrosion results showedthat the coating obtained at 60 mA/cm2 and pH 6 obtained the noblest corrosion potential(-0.5 V) and the highest polarization resistance value (20.00 Ω.cm2), presenting, therefore the highest resistance to corrosion.

Effect of EBW process welding parameters on AISI304L stainless steel bead geometry

Tiago Turcarelli[1], Fabio de Camargo[2], MAURICIO MARTINS DAS NEVES[1]

[1]Instituto de Pesquisas Energéticas e Nucleares (*Tecnologia Nuclear - Materiais*) , [2]Amazônia Azul Tecnologias de Defesa S.A. (*Laboratório de Degradação de Materiais*)

e-mail: tiago.turcarelli@gmail.com

One important field in the welding researches is the study of the relationship between the welding bead geometry and welding machine parameters. In electron beam welding (EBW) process, the fine controlled parameters enable a detail understand of the weld profile. EBW provides a concentrated beam of energy which can result in a high ratio of weld depth to bead width, which can be called a keyhole. EBW is widely study because of its importance in nuclear and aerospace application, mainly as a result of keyhole bead geometry. The relationship between the welding bead geometry, width root and depth with welding machine parameters is presented in this work by setting beam current and beam deflection frequency. All experiments were carried out on samples of AISI 304L alloy with a thickness (t) = 10 mm, accelerating voltage U = 60 KV, beam current range I = 34 - 43 mA, welding speed v = 480 mm/min, vacuum p < 10-4 mbar, beam deflection width d = 1.2 mm and beam deflection frequency f = 400 / 600 Hz. The weld joint geometry has changed by varying of beam current and beam deflection frequency. The weld penetration was increased by increment of beam current and deflection frequency. Set the frequency at f = 600 Hz and changing the beam current from 34 mA to 39 mA, it was observed that penetration rise from 7.38 mm to 8.46 mm, respectively. On the other hand, when was modified deflection frequency from 400 Hz to 600 Hz, the average welding penetration surged 6.3%. Moreover, with deflection frequency kept in f = 400 Hz, a beam current increment from I = 37 mA to I = 43 mA led to grow the welding penetration from 7.56 to 8.63, respectively. The results of weld width root showed no variation due to an increase of beam current, however applying a change of electron beam deflection frequency from 600 Hz to 400 Hz was verified a slight increase in it. In conclusion, the welding bead geometry is directly affected by varying of current beam and deflection frequency parameters.

EFFECT OF HEATING RATE ON THE KINETICS OF MARTENSITIC TRANSFORMATION OF NI-TI-HF ALLOYS: A STUDY USING DIFFERENTIAL SCANNING CALORIMETRY (DSC)

Walman Benicio de Castro[1], Glauco Ruben de F. Brito[2]

[1]Universidade Federal de Campina Grande (*Engenharia Mecânica*) , [2]Universidade Federal de Campina Grande (*PPGEM*)

e-mail: walman.castro@ufcg.edu.br

There are some alloys with shape memory of the Ni-Ti system considered as HTSMA (High Temperature Shape Memory Alloys). This occurs because a third element (Ni-Ti-X) is added to them, which, depending on the processing used, can obtain martensitic transformation temperatures (MS) above 100°C. Examples of these alloys include: Ti-Ni-Pd, Ti-Ni-Ta, Ti-Ni-Au, Ti-Ni-Hf. Hf is a more economically viable chemical element among those cited as thethird component of these ternary alloys. Thus, it was chosen for this work because of the possibility of these alloys being applied as a sensor/actuator in systems where martensitic transformation temperatures above 100°C are required. The $Ni_{50}Ti_{36}Hf_{14}$ (%at) alloy was prepared in an arc melting furnace. The transformation kinetics analyzes were carried out in a Differential Scanning Calorimeter (DSC) with heating rates of 2.5 °C/min, 5°C/min, 10°C/min and 20°C/min in the range of temperature between -30°C to 400°C and the startand end temperatures of the transformation varied according to the composition of thealloy. The results obtained for martensitic transformation (MS) temperatures during heatingconfirmed the Kolmogorov-Johnson-Mehl-Avrami Model (KJMA) pattern for a process mediated by nucleation and growth. Transformation enthalpies increased as heating ratesincreased.

Effect of Mg addition on the primary and secondary dendritic spacing of Al-4.5wt.%Cu alloy

Understanding the solidification process in manufacturing metal parts and components seeks to optimize structural characteristics and, consequently, the performance and quality of the product obtained. The dendritic microstructure found in solidified alloys is a consequence of the instability of the solid-liquid interface during phase change and directly affects the thermal and mechanical properties of materials [1,2]. Associated with this, chemical elements added to an alloy also influence the thermophysical characteristics of the material obtained. The Al-Cu system, especially with the copper content ranging from 2% to 5%, offers high mechanical strength and hardness when subjected to heat treatments. The low specific weight, allied to such properties, has made this torque a very interesting alternative in the manufacture of products for the automotive and aeronautic industries, such as cylinder heads and engine blocks. Adding Mg to Al strengthens the alloy not only through a solid solution strengthening, but also through a substantial dispersion strengthening mechanism through the formation of Al_2Cu and Al_2CuMg phases by heat treatment [3]. The main purpose of this work is to investigate the effect of Mg on primary and secondary dendritic arm spacings, respectively λ_1, λ_2, of an Al-4.5wt%Cu alloy horizontally solidified under transient conditions. The obtained results show significant changes between the observed microstructures of studied alloys, i.e., the addition of 1% Mg increased the $\lambda_1$values in Al-4.5wt%Cu-1wt%Mg as well as second phase particles are formed according to MEV.

Effect of Nb and Ti additions on phases, microstructure and hardness of equimolar AlCoCrFeNi high-entropy alloy

Filipe Caldatto Dalan[1], Rafael Kenji Nishihora[2], Rodrigo Morato de Souza Perfi[2], Sydney Ferreira Santos[2], Argemiro Soares da Silva Sobrinho[3], Katia Regina Cardoso[1]

[1]Universidade Federal de São Paulo (*Instituto de Ciência e Tecnologia*) , [2]Universidade Federal do ABC, [3]Instituto Tecnológico de Aeronáutica

e-mail: caldatto.filipe@gmail.com

The AlCoCrFeNi is one of the most investigated and promising high-entropy alloy (HEA) systems, due to its excelent synergy between phases control composition and properties [1]. The properties of this alloy can be improved by the addition of a sixth element in this system, among which the transition metals such as Cu, Mo, V, Nb and Ti are the most remarkable [2]. The aim of this work was to study the effect of Nb and Ti additions on the phases constitution, microstructure and hardness of equimolar AlCoCrFeNi HEA. The CALPHAD method using Thermo-Calc® software was employed for to compare and investigate the phases predicted by thermodynamic calculations with those obtained experimentally in ingots produced by arc melting. The phases and microstructure of as- casted samples were characterized by X-ray Diffraction (XRD) and by Scanning ElectronMicroscopy with Energy Dispersive Spectroscopy (SEM-EDS). The Vickers Hardness (HV) map and nanoindentation were performed and the results were related with the microstructure. The results of XRD and SEM-EDS analyzes agreed with the Thermo-Calc calculations, showing that the alloys are composed by solid solutions formed at high temperatures, presenting the ordered BCC-B2 as dominant phase. Nb additions leads to the formation of the Laves phase, while increasing the amount of Ti leads to the formation additional complex phases resulting from the BCC-A2 decomposition. The lattice parameter of the alloys increased with de Nb and Ti additions, due to the large atomic radius of these elements, which consequently result in a increase in hardness by the solid solution streghthening mechanism. The hardness of the AlCoCrFeNi alloy increased from 461 HV to 591 HV and 790 HV with the addition of Ti and Nb, respectively.

e-mail: hugoodeveza@gmail.com

Niobium plays an important role in the production of metallic alloys due to its high melting point, resistance to acid attacks and superconductivity at elevated temperatures [1]. This study analyzed the effects of the solidification and heat-treating parameters on the microstructure and the wear resistance of the Al-3wt.%Cu-5wt.%Nb. To achieve this, the alloy was obtained via unsteady-state solidification using a water-cooled horizontal solidification device. The investigated solidification variables were the growth and cooling rates ($V_L$and T_R, respectively). Samples obtained from the resulting ingot were analyzed both in the as-cast state as well as after being submitted to a T6 heat-treatment (T6-HT) which consisted of 3 hours of solution treatment at 490°C and 3 hours of artificial aging at 155°C. It was found that there were no significant changes in morphology of both the niobium andAl_3Nb before and after the T6-HT, however, it was able to effectively remove the copperfrom the interdendritic and intergranular regions and precipitate it inside the aluminum matrix, which grants the alloy greater resistance. The only way through which copper remained in such regions was when it combined with trace amounts of iron left over fromthe aluminum production process, as well as with niobium, forming intermetallic phases insusceptible to the heat-treatment. Such greater resistance was evidenced by the wear tests results, which showed that the T6-HT was ultimately able to decrease the wear rate ofthe investigated alloy by around 30% when compared to its as-cast state.

Effect of sputtering pressure on the physical propertiesof Zr-based metallic glass thin films

Bruno Lourencio Dias dos Santos[1], Alisson Carlos Krohling[1], Waldemar Augusto de Almeida Macedo[1]

[1]Centro de Desenvolvimento da Tecnologia Nuclear

e-mail: bruno.lourenciods@gmail.com

Amorphous metals, also known as metallic glasses, are materials that exhibit good thermal and electrical conductivity, corrosion and wear resistance [1], and a high Young's modulusdue to their lack of lattice structure. As thin films, these materials can be very interestingfor coatings [2], micro-electromechanical systems [3], and flexible strain sensors [4], amongother potential applications. We are investigating the preparation and properties of Zr- based metallic glass thin films grown by sputtering, for coatings and wearable sensors. Wewill discuss the effect of the Ar pressure during deposition - the working pressure - on thephysical properties of thin films from targets of Zr67Fe33 and Zr55Cu30Ni5Al10 alloys. Thethin films, 200 nm thick, were prepared using DC magnetron sputtering and at chamberworking pressures of 0.4, 0.63, and 1.0 Pa. It is expected that these conditions induce structural and morphological changes in the samples that result in modifications in theirproperties. The obtained films were characterized by X-ray diffraction, X-ray fluorescence, X-ray photoelectron spectroscopy, scanning electron microscopy, 57Fe Conversion electron Mössbauer spectroscopy (Zr67Fe33), and electrical measurements. The corrosion resistance was assessed through potentiodynamic polarization curves. The influence of the working pressure on the microstructure, corrosion behavior, and electrical properties of the films will be presented and discussed.

Acknowledgments:Financial support from CNEN, CNPq, CAPES, and FAPEMIG is gratefully acknowledged.

Effect of the hydrolysis time on the corrosion resistance of AA2024-T3 anodized in TSA and sealedwith hybrid coatings

Oscar Mauricio Prada Ramirez[1], Thassia Felix de Almeida[1], Hercílio Gomes de Melo[1]

[1]Universidade de São Paulo (*Departamento de engenharia metalúrgica e de materiais*) *e-mail: oscarmprada@usp.br*

Chromium-based anodizing and posttreatment steps are usually employed in the aircraft industry. However, despite offering good corrosion resistance and self-healing properties, as chromate compounds are toxic to health and the environment, chromium-based surface treatments will be prohibited in the aerospace industry soon. Tartaric-sulfuric acid (TSA) anodizing is a promising environment-compliant alternative, which is already being used at the industrial level. However, the corrosion resistance of the anodized layer alone is not sufficient to guarantee the required safety levels for an aircraft and more complex systems should be employed. In this investigation, AA2024 T3 specimens were anodized in TSA and subsequently sealed by a hybrid sol-gel coating (tetraethoxysilane (TEOS) and 3-glycidoxypropyltrimethoxysilane (GPTMS)), which hydrolysis solution was aged for different times. The morphology of the sealed anodic films and their thicknesses were evaluated by field emission scanning electron microscopy (FE-SEM) and Rutherford backscattering spectroscopy (RBS). The aging of the hydrolysis solution was followed by FTIR spectroscopy. The corrosion resistance of the samples was evaluated by electrochemical impedance spectroscopy (EIS) and salt-spray tests. FE-SEM characterization showed good coverage of the anodized surface by the hybrid layer. EIS experiments demonstrated improved corrosion resistance for increased hydrolysis time, and good responses were obtained for up to six months of aging. The relatively long shelf life of the hydrolysis solution is a good prospect for future industrial use of the hybrid coating.

Effects of growth and cooling rates, and secondary dendritic spacing on the electrochemical corrosion resistance of an AlCuNb alloy

e-mail: heldercaldasrodrigues@gmail.com

Al-Cu alloys are generally less corrosion resistant than other alloys. In these alloys, intermetallics of Al_2Cu, Al2CuMg, and Al_7Cu_2Fe are some of those responsible for initiating galvanic corrosion with the matrix [1]. Niobium at room temperature resists well to the action of hydrochloric (up to 35%), sulfuric (up to 95%), concentrated nitric, phosphoric, chromic, acetic, formic and citric acids. It has resistance to corrosion due to the formation of a superficial oxide film responsible for its passivation [2]. In this sense, the main objective of this work is to evaluate the effects of solidification thermal parameters (STP) and the length of the microstructural scale, such as growth and cooling rates (VL and TR), and secondary dendritic spacing (λ_2) on the corrosion resistance (CR) of horizontally solidified Al-3Cu-0.5Nb alloy (wt.%) using a water-cooled device. Electrochemical measurements of corrosion potential (Ecorr) variations with time and potentiodynamic polarization curves were obtained in a 0.2 M HCl electrolyte (25 ºC). The corrosion tests were carried out attwo positions in relation to cooled interface of the studied alloy (10 and 70mm). The results indicated that in the position 70 mm of the cooled wall the corrosion density (Icorr) increase and shows minimum shift of the Ecorr in the negative potential direction. This work demonstrates that the $\lambda_2$is a very important factor to influence CR.

Electrochemical behavior of Cu-9Al-2Mn-xSn alloys

Jefferson da Silva Augusto[1], Mariana dos Santos Costa[1], Leandro Santos da Silva[1], Ricardo Alexandre Galdino da Silva[1]

[1]Universidade Federal de São Paulo (*Departamento de Química*)

e-mail: augusto27@unifesp.br

Copper-rich Cu-Al-Mn alloys are widely studied due to their mechanical and thermomechanical properties. The presence of Mn in these alloys, combined with low content of aluminum, improves the ductility and increases the temperature at which martensitic transformation occurs. Moreover, Cu-based alloys show corrosion resistance that allows the application in industrial devices such as suction pumps and in naval industry[1-2]. In this study, different Sn contents were evaluated in the Cu-9%Al-2%MnX%Sn alloys(X = 0.5, 1, 2, 4, and 6). The corrosion resistance in 0.5 mol L^{-1}NaCl of the aforementionedalloys, as well as the relationship between this property and the phases composition, werestudied using X-ray diffraction, optical microscopy, cyclic voltammetry, open circuit potential, and potentiodynamic polarization. The results showed that there is a grain refinement when the Sn content increases. In addition, at higher concentrations than 2%Sn, a new phase is formed in the alloys. Corrosion potentials became more positive with theSn addition, but the corrosion current densities increased up to 1.0% Sn and then decreasedat higher concentrations. This suggests that the initial increase in tin content impairs the corrosion resistance of the materials, which may be related to the formation of new phasescontaining this element. Further increase in tin content reduced the quantity of phases inthe alloy. There is evidence that the presence of tin modifies the well-known copper oxidation mechanism in a 3.5% NaCl solution.

e-mail: evandro.zanni@hotmail.com

In the present study, the electrochemical corrosion behavior of laser-welded dissimilar steel joints was evaluated. SAE 300M is an ultra high strength steel and used in the aerospace industry due to its high resistance [1]. Dual-phase DP600 belongs to the grade of advanced high-strength steels whose development resulted from the automotive industry's need for low-cost sheet material [2]. The fiber laser welding process was employed as this type of welding is faster and cleaner than other processes, with minimal change to the steel's microstructure. The welding parameters applied were 1800 Watts of power and 50 mm/s of speed to join the SAE 300M and DP600, with a sheet thickness of 2.7 and 2.2 mm, respectively. After welding, the welded joints underwent three types of heat treatments: tempering, quenching and tempering, and intercritical quenching. Potentiodynamic polarization measurements were performed in a 3.5 wt.% NaCl solution at 25 °C to evaluate corrosion behavior of the welded joints. The findings about corrosion behavior revealed that the Fusion Zone (ZF) is more prone to suffer the effects of corrosion than steels surrounding this region, either in 300M or DP600 steel. For untreated welded joints and tempering treatments, the rate registered for annual corrosion is low with little change in mass loss and welded joint's lifetime, being 0.44 mm per year for untreated condition and 0.60 mm per year for tempering condition. For the intercritical tempering, tempering and tempering treatments, the value was more relevant, the corrosion rate was higher, the mass loss was around 10 fold higher than the other conditions, reducing the useful joint’s lifetime.

Acknowledgments: This research was carried out with the support of CAPES and members of the Mechanics group at ITA.

e-mail: flaviofavaro@estudante.ufscar.br

The Microscopy School is a specialization course offered by the Structural Characterization Laboratory (LCE), of the Materials Engineering Department at UFSCar. This course is annually offered, and its main results, impacts and outcomes will be showcased. The course is being offered for more than 20 years and is attended by professionals from engineering, physics, chemistry, and biological sciences fields. The Microscopy School provides training on several microscopy techniques, including transmission and scanning electron microscopy as well as other characterization techniques such as x-ray diffraction. Participants receive hands-on training on sample preparation, instrument operation, and data analysis, which enhance their understanding of material structure and properties. The course was reported to be highly beneficial to undergraduate and graduate students, as well as researchers from industries and research centers in Brazil. The Microscopy School offered participants the opportunity to acquire state-of-the-art knowledge and skills, which they could apply in their research projects, contributing to the advancement of the scientific and technological development of the country. The training also promoted the transfer of knowledge and technology between academia and industry, which is essential for solving real-world problems. A summary of the main activities performed during the course as well as summaries of reviews of the course will be presented. The structure of the course will be showcased and the strategy used to be a useful course for both academia and industry. In conclusion, the Microscopy School offered by the LCE of UFSCar is being successful in providing quality training to professionals from different fields, promoting knowledge exchange and enhancing the scientific and technological development of the country.

Enhanced electronic transport properties of Te roll-like nanostructures.

Emilson Ribeiro Viana[1], Nestor Cifuentes[2], Juan Carlos González[2] [1]Universidade Tecnológica Federal do Paraná (*Departamento Acadêmico de Física (DAFIS-CT)*), [2]Universidade Federal de Minas Gerais (*Departamento de Física*)

e-mail: emilsonjunior@utfpr.edu.br

In this work, the electronic transport properties of Te roll-like nanostructures were investigated in a broad temperature range by fabricating single-nanostructure back-gated field-effect-transistors via photolithography. These one-dimensional nanostructures, with a unique roll-like morphology, were produced by a facile synthesis and extensively studied by scanning and transmission electron microscopy. The nanostructures are made of pure and crystalline Tellurium with trigonal structure (t-Te), and exhibit p-type conductivity with enhanced field-effect hole mobility between 273 cm^2/Vs at 320 K and 881 cm^2/Vs at 5 K. The thermal ionization of shallow acceptors, with small ionization energy between 2 and 4 meV, leads to free-hole conduction at high temperatures. The free-hole mobility follows a negative power-law temperature behavior, with an exponent between −1.28 and −1.42, indicating strong phonon scattering in this temperature range. At lower temperatures, the electronic conduction is dominated by nearest-neighbor hopping (NNH) conduction in the acceptor band, with a small activation energy $E_{NNH} \approx 0.6$ meV and an acceptor concentration of $N_A \approx 1 \times 10^{16} cm^{-3}$. These results demonstrate the enhanced electrical properties of these nanostructures, with a small disorder, and superior quality for nanodevice applications.

In recent years, world population growth has generated a great demand for new technologies that can serve strategic areas such as energy, healty, food, transport. Regarding the energy matrix, there is a movement that looks for alternatives to replace the energy matrix based on fossil fuels. In this sense, biofuels are considered a good alternative, mainly because they present an environmentally friendly behavior [1-2]. Among the different types of biofuels, biodiesel is the main option to replace fossil diesel, however, biodiesel has disadvantages such as being susceptible to oxidative degradation, more hygroscopic and generally more corrosive than diesel [1-4]. Considering the high costs of corrosion and the greater corrosivity of biodiesel, research has been carried out to understand the behavior of different metallic alloys exposed to biodiesel and to evaluate compounds that act as antioxidants, maintaining the stability of biodiesel and reducing corrosion [1-4]. This work evaluated the effect of adding citronella essential oil on the corrosion inhibition of two metal alloys: carbon steel and copper alloy in contact with soybean biodiesel. Immersion tests at temperature of 25°C were carried out and made it possible to calculate the corrosion rate of the metallic alloys and the efficiency of inhibition of the essential oil. It was observed that the essential oil acts as a corrosion inhibitor for both carbon steel and copper alloy, however the effect was more significant for steel.

EVALUATION OF DEFORMATIONS OBTAINED IN THE TENSILE TESTING USING CORRELATE GOM SOFTWARE

SANDRO ROSA CORRÊA[1], ARTHUR DA SILVA MEDEIROS[2]

[1]Centro Universitário de Volta Redonda (*Engenharia Mecânica*) , [2]Centro Universitário deVolta Redonda (*Engenharia de Produção*)

e-mail: sandro.correa@foa.org.br

This study consisted of the implementation of the Digital Image Correlation (DIC) method, using the GOM CORRELATE 2D software provided by the German company GOM [1]. This application allowed the realization of more simplified, accurate, true, low-cost and easy-to-implement analyses, consistent with the state of the art for these applications in companies that work with material stamping. The ease of the technique allowed the use of cameras found on smartphones, to survey the deformations that occurred during the tensile test, in a controlled manner on the specimens. To carry out the tests and validate the technique, a high-strength cold-rolled steel was used, applied in the segment of auto parts, where samples were taken in the transverse direction of the lamination, and they were made in accordance with the ASTM A 370 standard [2]. Afterwards, layers of spray paint were applied, the first being white and then drying, a black layer with the intention of creating a random pattern, but uniformly on the surface of the specimen for the uniaxial tensile test. The tests were carried out in the EMIC equipment model DL 10000 of 100kN. The images obtained sequentially during the traction test of the specimen, previously painted, were loaded into the software and, after configurations and parameter adjustments, generated graphic images with value scales. The regions where the greatest deformations occurred in the tensile test were shown through the algorithms of the Digital Image Correlation technique to describe the behavior of the material. The product of this work was the elaboration of a procedure for using the GOM CORRELATE 2D software in the UniFOA laboratory.

The self-healing mechanism through electrical pulses is an effective alternative to promote the regeneration of microstructural defects in offshore oil industry metallic structural materials. It assists in atomic diffusion, stress relief, dislocation movement, microcrack closure and even recrystallization in some cases [1-2]. The effect of electrical pulses was analyzed on specimens of the AA5083-H112 alloy with a cross section of 15 mm^2, which were submitted to tensile tests to promote microstructural defects and then submitted to self-healing. Defects were generated with a pre-strain of 80% of the rupture strain. The pulses were emitted in closed circuit with an adapted welding source, model DigiPlus A7 600 in pulsed TIG mode. The peak current was 400A and base current 0A, with periods of 0.1s each. The complete pulse emission time ranged from 0s, 7s and 15s. The samples were resubmitted to tensile tests and evaluated. There was a small thermal effect reaching up to 142.50 ºC. The application of a current density of 26.67 A/mm^2proved to be effective in promoting an increase in ductility. The resulting deformations in the pre-deformed samples, after 0s, 7s and 15s of electrical pulses was 7.60%, 9.02% and 11.02%, respectively, indicating a significant gain in ductility. The microstructural characterization via SEM corroborated the evidence of the effect that occurred on the observed microstructural defects.

e-mail: giuliana.taissa@ufpe.br

Copper is widely used in the electricity and civil construction sectors, however it is susceptible to corrosion when exposed to aggressive environments [1]. Phosphatization pretreatment is a method that has been employed on various metal substrates to delay the corrosion process and improve the adhesion of coatings to the substrate through the formation of a porous layer of insoluble precipitates [2]. Phosphated and coated steel surfaces has been addressed in several studies, but investigation of protective methods for copper substrates is not widespread. Electrodeposited nickel coatings have been widely used due to their excellent properties to increase corrosion resistance, low-cost, high-efficiency and easy-to-perform process [3]. The aim of this study was to evaluate the influence of phosphatization on electrodeposited nickel coatings on copper substrates. For this, surface characterizations were performed under four conditions: uncoated substrate (C00), phosphatized substrate (C00F), substrate coated with electroplated nickel (C10), and phosphatized substrate subsequently coated with electroplated nickel (C10F). Morphological analysis of the obtained surfaces was performed through SEM and qualitative elemental composition was determined through EDS. Wear resistance was determined using a linear module tribometer with a 1 N load. Corrosion resistance properties were analyzed by potentiodynamic polarization test in 3.5% NaCl solution. The prior phosphatization of the surface resulted in a nickel coating with more lamellar structures on a smaller scale, showing improved corrosion and wear resistances.

Evaluation of metal oxide nanoparticle films on steel corrosion: selection of important variables

Aline Borges de Andrade[1], Tatiane Moraes Arantes[2], Gildiberto Mendonça de Oliveira[3]

[1]Universidade Federal de Jataí (*PPGQ*) , [2]Universidade Federal de Goiás, [3]Universidade Federal de Jataí

e-mail: alineborges41@hotmail.com.br

The use of nanoparticles has been contributing to a technological advance in the industrial processes, as in the case of corrosion protection. In this sense, the objective of this research is to investigate the effect of nanoparticles of SiO2, TiO2, ZrO2, and their mixtures as inhibitors of the corrosion process of 1020 steel, using thin films obtained by dip coating. Dip-coating technique has been widely used in metallic surface coating processes with film formation that lead to corrosion protection [1]. In general, the films are obtained with: a solution withdrawal speed of 10cm/mi three immersio film drying temperature of 60°C for one hour, between each immersions and using distilled water as solvent in the dispersion of nanoparticles. The time of immersion has not being shown as an important variable. However, the temperature for the thermal treatment of the films at various times affects the corrosion inhibition, normally being tested at 500°C and 800°C with 1h and 2h [2-3]. Another relevant aspect is that each solution composition (concentrations and components) leads to different inhibition effects, also verifying that the mixture and proportion between components are also of extreme importance. In general, can be checked mixtures with 70%SiO2 and 30% TiO2 or ZrO2. In order to verification the corrosion rate are employees open-circuit potential tests and polarization curves. Considering these aspects of the literature, this work seeks to apply factorial planning as a tool to evaluate the best experimental condition to corrosion inhibition using SiO2, TiO2, ZrO2 components, of the fims obtaindeby dip coating.Acknowledgements: CAPES, PPGQ/UFJReference: [1] S. EVALUATION OF MURUMURU BARK POWDER AS CORROSION INHIBITORS FOR CARBON STEEL INACID MEDIUM

Gustavo Dias Soares[1], Lhaira Souza Barreto[1,2], Marco Antônio Barbosa de Oliveira[3], Vera Rosa Capelossi[1]

[1]Universidade Estadual de Santa Cruz, [2]Universidade Federal de Pernambuco, [3]Instituto Federal de Educação, Ciência e Tecnologia do Pará

e-mail: gdsoares.egq@uesc.br

Corrosion is a spontaneous process of deterioration of metals that is very common on a daily basis, especially in coastal regions. This fact causes great economic and environmental damage to society, then there is a need to use corrosion inhibitors. As a sustainable and economically viable alternative, natural corrosion inhibitors extracted from plants appear. This work aims to study the efficiency of murumuru bark powder as a corrosion inhibitor on SAE 1008 carbon steel in 1M HCl acid medium. To evaluate the inhibition efficiency, electrochemical impedance spectroscopy (EIS), gravimetric techniques and polarization curves were performed. Fourier Transform Infrared Spectroscopy (FTIR) was performed for chemical characterization. Through the results of the EIS it was observed that the presence of the inhibitor confers protection against corrosion and an efficiency of 78.2% for the concentration of 1.77 g.L-1. Analyzing the polarization curves, murumuru bark powder is an inhibitor that presents a mixed behavior [1]. The results of the gravimetric tests corroborate the electrochemical tests when they present an efficiency of 66.2% at the concentration 1.77 g.L-1. The FTIR assay showed the presence of hydroxyls and other functional groups in the inhibitor structure that may be responsible for inhibiting this corrosive process. In this way, it can be inferred that the Murumuru bark presents an inhibitory characteristic of corrosion in acidic medium in carbon steel SAE 1008.

Evaluation of steel alloys applied in roller presses for comminuting ores

João Vitor Roggenbach de Oliveira[1], Edson Luiz da Silva Junior[1], João Pedro Valls Tosseti[1], Kahl Dick Zilnyk[2]

[1]Instituto Tecnológico da Aeronautica (*Engenharia Mecânica e Aeronáutica*) , [2]Instituto Tecnológico da Aeronautica (*Eng. Aeronáltica e Mecânica*)

e-mail: joaorogg@outlook.com

Reducing manufacturing costs is a crucial goal for the metallurgical sector, and one approach is to replace a material with a more affordable alternative that is equally or more effective. This study aims to investigate the feasibility of substituting a specific material, used in comminution rollers, with a large-scale produced tool steel. The materials studied include the current roller mill steel, 18NiCrMo14-6, and the modified H11 tool steel, both of which underwent equal heat treatment procedures. Normalized at 920°C, followed by a temper at 600°C, quenched in water and again tempered at 540°C. The primary distinction between the alloys is the reduction in carbon and nickel content, which is prevalent in the current steel, compensated by an increase in chromium, vanadium, and molybdenum content in the tool steel [1]. The microstructural analysis, performed using SEM and optical microscopy, revealed that both materials possess bainitic and martensitic structures despite having different alloying elements [2] [3]. The hardness values of the two materials were similar, with around 40 HRC for each. Finally, the tensile and impact tests demonstrated that the tool steel is a feasible substitute.

e-mail: kesiasimoesribeiro@gmail.com

Stainless steels are widely used in the industrial environment due to their special properties such as mechanical and corrosion resistance. The 316L stainless steel has been used in the manufacture of the equipments for the chemical, petrochemical and pharmaceutical industries [1-2]. The corrosion resistance of stainless steels is mainly due to the presence of the oxide film spontaneously formed on the metallic surface and that provides protection by passivation. However, in the presence of an aggressive environment, such as chloride ions presence, in addition to other factors such as temperature and pH of the corrosive medium, these materials can become susceptible to different types of corrosive processes [2-3]. Considering the costs of the corrosion and the wide range of applications for 316L steel, this work evaluated the effect of different environmental conditions on the susceptibility to corrosion of 316L steel. The steel samples were analyzed in three corrosive media that simulate different aggressiveness: 3.5% NaCl, 3.5% $Na_2SO_4$and 3.5% HCl. The samples were exposed to the medium at two different temperatures: 25° and 70° C. The corrosion resistance was evaluated through electrochemical and immersion tests. The results showed that the 316L steel showed lower corrosion resistance in the presence of chloride, especially at acid medium. In tests at room temperature, the presence of pitting corrosion was observed. Immersion tests at a temperature of 70 ℃ showed the presence of uniform corrosion in addition to pitting. In sulfate medium, no significant corrosive processes were observed on the surface of the sample.

Waste from Electrical and Electronic Equipment (WEEE) has been raising increasing environmental concerns due to the rapid technological evolution and the growth of electronic consumption. These wastes may contain high-value metals, such as gold, silver, palladium, and rare earth metals, as well as potentially toxic metals, such as lead, cadmium, mercury, and arsenic, which are harmful to the environment and human health. In this context, hydrometallurgical techniques for recovering these metals can be employed in the minimization and remediation of environmental problems associated with metals. Thus, this study investigated the efficacy of ethylenediaminetetraacetic acid (EDTA) in removing potentially toxic metals, such as copper, lead, zinc, nickel, and aluminum from milled wastes of printed circuit boards (PCBs) from computers. The initial mass of metals in the waste was determined through digestion of the milled PCBs in aqua regia, followed by an analysis using inductively coupled plasma optical emission spectrometry (ICP-OES). To extract the mentioned metals, EDTA was used at a concentration of 0.6 M and a temperature of 80°C. The results demonstrated that EDTA has the potential to recover metals from PCBs, showing an extraction content of up to 54.1%, 33.1%, and 44.0% for aluminum, lead, andzinc, respectively. The application of EDTA may contribute to sustainable practices of hydrometallurgical techniques employed in electronic recycling, as well as reducing the cost of reagents and the environmental impact caused by the disposal of effluents generated using other leaching agents.

Evolution of Residual Stress on AISI D2 tool steel short time tempering

Maycoln Depianti Conci[1], Rene R. Oliveira[2], Dany Michell Andrade Centeno[3], Hélio Goldenstein[3], Paula Fernanda da Silva Farina[4]

e-mail: mdconci@gmail.com

Some parameters are used in an attempt to estimate a relationship between time and tempering heat treatment temperature of steels, among which the Hollomon-Jaffe parameter stands out [1]. This work aimed to study the evolution of residual stresses in short-time tempering treatment of AISI D2 tool steel, compared to conventional heat treatment of tempering [2]. The samples were treated in dilatometry for a better control of the thermal processing variables. Microstructural images were generated using optical and scanning electron microscopy, including mapping using EDS. Vickers microhardness measurements were performed. And the measurements of variations in residual stresses in each of the treatment stages and at the end of the treatment cycles were performed by analyzing the X-ray diffraction data using the Sen2Ψ technique [3]. The cycles composed of tempering in short times carried out at 500 ºC or 600 ºC, for 10 seconds or 1 minute, exhibited residual stress states similar to the conventional cycle, with a tendency towards neutrality of the residual stress state and high hardness values. The final residual stresses acquired by the AISI D2 tool steel in the thermal cycles studied, more specifically in the tempering, can be attributed to the precipitation of tempering carbides, which when carried out up to 600 ºC, occurs coherently, or at least partially coherently, to the matrix, producing the neutrality of residual stresses, but when tempering is carried out at 700 ºC, it leads to incoherent precipitation of carbides and matrix recrystallization, leading to an increase in compressive residual stresses and a reduction in the hardness of the material, regardless of the heat treatment time of tempering.

e-mail: jessica.vluiz@usp.br

Currently, a new class of metallic alloys, known as high entropy alloys (HEAs) or multi-principal element alloys (MEAs), is being investigated by the scientific community. These alloys combine five or more elements in equiatomic or semi-equiatomic proportions. Aiming at structural applications at high temperatures, such as in the aerospace industry, metals with high melting point and relatively low density are important constituents of these alloys. In this context, the Cr-Nb-V system, object of the present study, is a key ternary to develop multi-principal element alloys for high temperature applications. As little information is available for this system, an isothermal section at 1100 °C is proposed for the first time in the literature based on the results of experimental investigation in this work. This proposal is based on the microstructural characterization of 25 alloys, which were arc-melted under argon, heat-treated at 1100 °C for 20 days, carried out by scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS), and X-ray diffractometry (XRD). The results showed that the maximum solubility of vanadium in the C15 Laves phase is approximately 34 at.%, which is compatible with the increase in vanadium solubility with decreasing temperature indicated in isothermal sections at different temperatures (1350 and 1000 ºC) published in the literature [1,2].

This work deals with the failure analysis of rear differential shaft of a sugar cane loader that broke in a little less than three years of service. For the analysis of fracture, were realized fracture surface macrographs, and microhardness profile metallographic analysis. Was also carried out numerical simulation of shaft estimating reliable way external efforts suffered during use. For this numerical simulation was performed in linear elastic regime. The microstructure is in agreement with the manufacturer. The surface hardness was 60HRC according to which the manufacturer presented. The failure occurred by high cycle fatigue and we observe various nucleation points to a singularity near the radius of curvature of the shaft. The numerical simulation was possible to quantify the tensions and showed us that this singularity in the axle base was what caused tension concentrations that result in the failure of the component.

Generalized Quasichemical Approximation applied to superconducting materials

Luiz Tadeu Fernandes Eleno[1], Pedro Pires Ferreira[1]

[1]Universidade de São Paulo (*Escola de Engenharia de Lorena*)

e-mail: luizeleno@usp.br

The search for new, efficient superconductors has been a central focus of research in solid-state physics and chemistry for some time. To predict the behavior of these materials, it is crucial to develop efficient models for their thermodynamics. In this study, we introduce an ab-initiostatistical model called the Extended Generalized Quasichemical Approximation (EGQCA) to investigate off-stoichiometric superconductors. Using EGQCA, one can predict physical properties, such as the critical temperature of any alloy as a function of composition and crystal growth temperature. The model evaluates the average of individual supercell properties weighted by their occurrence probabilities to minimize the overall mixing Gibbs free energy. We demonstrate the effectiveness of EGQCA by applying it to Al-doped MgB2, which shows excellent agreement with experimental data. Our open-access and user-friendly implementation of EGQCA makes it applicable to any 2D or 3D system, and enables high-throughput screening of complex high-Tcsuperconductors, providing insights into the interplay between synthesis and thermodynamics in these materials.

The project was financed by grant #2020/08258-0, São Paulo Research Foundation (FAPESP).

Graded NiAl/WC coatings

Heber Oswaldo Abreu Castillo[1], Ana Sofia Clímaco Monteiro D' Oliveira[2] [1]Universidade Federal do Paraná, [2]Universidade Federal do Paraná (*Engenharia Mecânica*)

e-mail: heberabreu@ufpr.br

NiAl intermetallic coatings have been used to protect superalloys from high-temperature operating conditions [1]. When processed in-situ through Directed Energy Deposition-Plasma Transferred Arc (DED-PTA), on AISI 304 austenitic stainless steel, high levels of dilution with the substrate are measured due to specific features such as the exothermal synthesis of β-NiAl phase [1]. This leads to the presence of large amounts of austenitic γ-FeNi phase, together with the aluminides. Increasing amounts of the austenitic phase, which has lower hardness, results in a decrease in the overall coating hardness, affecting the tribological properties [2]. The amount of γ-FeNi phase can be reduced by depositing multi-layers [3]. Furthermore, multi-layers can be processed offering gradual changes in composition, allowing to manufacture Functionally Graded Materials (FGMs). In this work, FGMs were processed by DED-PTA using Ni and Al powder mixtures with a gradual increase in WC content. Results show a reduction in the effects of the austenitic phase in the aluminide coatings. Also, the gradual increase of WC fraction in the powder mixtures induces multilayers with a graded functionality taking advantage of the microstructural changes and improvements in hardness and wear that a distribution of carbides provide.

e-mail: monique.osorio@fat.uerj.br

The emerging Green Chemistry area is the use of principles that reduce or eliminate the use or generation of hazardous substances in the design, manufacture and application of chemicals and envisages harm reduction as a performance criterion when designing new chemical processes. Green chemistry approaches to nanoparticle synthesis are one-step, fast, simple, low-cost, avoid toxic chemicals, and use non-toxic solvents such as water. Therefore, the use of plant extracts as a reducing agent in the synthesis of nanoparticles hasreceived increasing interest. Being easily reproducible and biocompatible, together with the availability of simple protocols, make this approach a favorable procedure for nanoparticle synthesis. In this context, this study aims to develop two types of metallic nanoparticles, based on Sn and Nb, from the use of Lycopersicon esculentum extract (tomato) through a route considered green [1,2]. These nanoparticles have the potential to be applied to capture gases and medical field. Afterwards, these nanoparticles will be characterized by UV-Visible spectroscopy, Fourier transform infrared (FTIR) spectroscopy, X-ray diffraction (XRD) measurements and scanning electron microscopy (SEM). The results showed that nanoparticles are promising for use as catalysts in gas capture systems.

e-mail: guicstumpf@gmail.com

In recent years the multi-principal element alloy (MPEA) design approach has gained a significant attention from the scientific community due to its vast range of possibilities. Face centered cubic (FCC) MPEAs, have demonstrated their potential for multiple engineering applications, including the Cr-Co-Ni alloy, which is one of the toughest materials known. This alloy's exceptional properties are attributed to the plasticity-induced deformation mechanisms, including twinning and phase transformation. However, there is still much that remains elusive in the understanding of the deformation and structural behaviors of MPEAs. Studies show that the slight local preference between the elements can lead to chemical fluctuations and even local chemical ordering (LCO) [1,2]. The stacking fault energy is highly dependent on the chemical composition, and thus, the deformation mechanisms can be impacted by these fluctuations [1,2]. To further investigate this, we manufactured a $Cr_{40}Co_{30}Ni_{30}$ alloy through arc-melting of the high purity individual elements. The material was thermo-mechanically processed multiple times with cold rolling followed by annealing. Then, the fully recrystallized sample was severely deformed via high pressure torsion (HPT). To analyze the material, we removed a thin foil for analysis from the near-border region of the disk using a focused-ion beam setup coupled on a scanning electron microscope. This foil was characterized in a transmission electron microscope with high-resolution energy-dispersive X-ray spectroscopy. Local chemical fluctuations were detected in both the sub-micrometer and atomic scales.

e-mail: anabrasil@usp.br

A new class of Ni-based superalloys was recently developed by optimizing the RR1000 alloy [1]. The chemistry of these alloys, designated by ABD-2, ABD-4 and ABD -6, differ by the partial replacement Ti by Nb. [2] studied the oxidation of these alloys at 800°C for 100 hand noticed an enhancement of the resistance with the increase of the Nb content. In thiswork, the effect of the Nb and Ti on the oxidation resistance was investigated for two alloys:
i) ABD-Ti having the same chemistry of the ABD-2 from [1], containing only Ti, and ii) ABD-Nb containing only Nb. The alloys were cast by arc-melting under Ar, solubilized at 1170°Cfor 2 h and aged at 850°C for 4 h. The oxidation tests were carried in isothermal andpseudo-isothermal conditions at 800 and 900°C. At both temperatures, the ABD-Ti alloy presented a parabolic kinetic with rate constants of $4.3E^{-7}$and $9.1E^{-6}mg^{2}.cm^{-4}.s^{-1}$at 800 and 900°C respectively. At 800°C, the ABD-Nb alloy showed a parabolic behavior at the beginning of the exposure up to 280 h. Near 300 h a kinetic transition takes place with astagnation of the mass change up to the end of the test. At 900°C the ABD-Nb followed aparabolic behavior with a rate constant of $1.7E^{-6}mg^{2}.cm^{-4}.s^{-1}$. For both alloys, the characterization by XRD indicated the presence of Cr_2O_3, $Al_2O_3$and $(Ni,Co)Cr_2O_4$for the specimens tested at 800 and 900°C. These results are corroborated by cross section micrographs that also showed the presence of internal Al_2O_3. For the ABD-Nb alloy oxidized at 800°C, XRD and SEM characterization showed the presence the δ phase in the subsurface region that can be formed by means of oxidation induced transformation and the formation a continuous Al_2O_3layer enhancing the oxidation resistance of the alloy.

Hydrogen is often suggested as an ideal substitute to fossil fuels in energy carrier applications. Developing more efficient and safe hydrogen storage systems might be the key factor to facilitate its applications. Solid state storage via metal hydrides is a suitable option, especially considering stationary applications. Multicomponent body-centered-cubic (BCC) alloys have been showing promising storage properties. However, the comprehension of the absorption/desorption reactions of these alloys is still in the early stages. In this work, we investigated the hydrogenation reactions of the Ti31,8V33,7Nb29,8Co4,7 multicomponent alloy. The alloy was produced via arc melting and it was characterized via Scanning Electron Microscopy (SEM) and X-Ray diffraction (XRD). The alloy was hydrogenated with different concentrations of hydrogen and subsequently characterized via XRD. Desorption reactions were analyzed via Thermal Desorption Spectroscopy (TDS) of the hydrogenated samples. The as-cast Ti31,8V33,7Nb29,8Co4,7 alloy presented a BCC structure with dendritic morphology. The XRD and TDS analyses of partially and fully hydrogenated samples indicate that the alloy presents the following hydrogen absorption/desorption reactions: BCC alloy ↔ BCC intermediate hydride ↔ FCC dihydride. Similar sequence of reactions has been reported for the (TiVNb)85Cr15 alloy in the work developed by Silva et al. [1]. However, in this work, the coexistence of two BCC phases at the intermediate level of hydrogenation was identified using only conventional laboratory XRD analyses.

[2]Universidade Federal de São Carlos (*Departamento de Engenharia de Materiais*)

e-mail: gabrielamayerdias@hotmail.com

Meeting global energy demands while minimizing environmental impact is an ongoing challenge. One promising solution is the use of hydrogen as an energy vector, which has a high gravimetric energy density and produces only water as a byproduct. However, safe and efficient hydrogen storage remains a critical barrier to its widespread use. Solid-state hydrogen storage through metal hydrides is a promising option and Ti-Nb-Cr is one of many alloy systems currently being researched, although only a few studies have explored its properties in depth. Therefore, this study aims to characterize and investigate the hydrogen storage properties of the equiatomic TiNbCr alloy. The alloy was produced by arc melting and a X-ray diffraction analysis revealed a body-centered cubic phase with a fraction of C15 Laves phase. The alloy absorbed hydrogen without prior heat treatment when exposed to 30 bar of H2 at room temperature, showing a maximum capacity of 2.80 wt% after an incubation time of 1 hour and 5 min of absorption. The application of heat treatment at 400°C for 2 hours under dynamic vacuum resulted in the absorption under 2 min with no incubation time. The XRD pattern obtained after the first hydrogenation at room temperature revealed a face-centered cubic phase along with the primary C15 laves phase. Additionally, the Pressure-Composition-Temperature (PCT) diagram was measured at temperatures ranging from 25°C to 150°C, showing a low plateau pressure of approximately 0.01 bar at room temperature.

e-mail: pedrofholiveira@hotmail.com

Equal Channel Angular Pressing (ECAP) at cryogenic temperatures has been adopted to increase the strain severity by suppressing dynamic recovery and accumulating crystalline defects. In this context, this study performed ECAP on a Cu0.7Cr0.07Zr alloy at room and cryogenic temperatures (-80°C) and analyzed its impact on microstructure and mechanical properties. Uniaxial tensile tests and Vickers hardness measurements assessed mechanical properties, while microstructural changes were evaluated using optical microscopy (OM), transmission electron microscopy (TEM), electron backscatter diffraction (EBSD), X-ray diffraction (XRD) and differential scanning calorimetry (DSC) analysis. The results showed that the material presented deformation twins after processing at both temperatures. Also, it was observed a decrease in grain size of around 94% and 88% after ECAP at room and -80°C, respectively, leading to a corresponding increase in hardness of 90% and 119%. Yield Strength also increased by 358% and 373% after ECAP at room and -80°C, respectively. However, these mechanical property improvements were accompanied by a reduction in the uniform elongation of 92% and 94% after ECAP at room and -80°C, respectively. Deformation twins was also observed after ECAP at both temperatures. Hence, the study highlights the effectiveness of ECAP at cryogenic temperatures in enhancing the mechanical properties of the Cu0.7Cr0.07Zr alloy.

INFLUENCE OF HEAT TREATMENT OF QUENCHINGAND TEMPERING ON H11 MOD TOOL STEEL

Cristiane Sales Gonçalves[1], ANDRÉ PAULO TSCHIPTSCHIN[2]

[1]Escola Politécnica da Universidade de São Paulo (*Engenharia Metalúrgica e de Materiais*) ,
[2]Escola Politécnica da Universidade de São Paulo

e-mail: cristiane.goncalves@villaresmetals.com

The heat treatment is a process that acts as a key factor in the tool life of tools made with hot work tool steels. Due to their applications, the main desirable metallurgical properties of this material class are toughness and hot resistance, without which the tools may suffer premature failure, and may lead to increases in the cost of producing articles made using such tools [1, 2]. Therefore, special attention must be given to the heat treatments practiced in these steels, whose operations involve quenching and tempering. The present work carried out the effects of the austenitizing and tempering temperatures on the microstructural condition, hardness and impact properties of modified AISI H11 with lower silicon content. Hardness was measured by the Rockwell method, C scale; the toughness was evaluated by the Charpy-V impact test; and the microstructure for each condition was evaluated by optic microscopy. It was shown that higher austenitization temperatures resulted in increased grain and hardness; higher tempering temperatures resulted in reduction of hardness, and secondary hardening peaks were observed for some austenitization conditions. The impact resistance showed an inverse behavior to that of the hardness, remaining initially constant, up to ~ 550 ° C of tempering temperature, and then increasing with the tempering temperature. The microstructures presented great dissimilarity, mainly due to the dissolution of carbon and alloying elements in the matrix. Another factor that impacts the final toughness of the material is the cooling rate during quenching; the higher it is, the greater the predominance of martensitic microstructure, obtaining greater resistance to impact. In the end it is possible to find the heat treatment that can balance good mechanical strength and good toughness.

Influence of light on the corrosive behavior ofcommercial alloys A356 and A413 used in the automotive wheels

Adriano Tonetti[1], Eder Lopes Ortiz[1], Giovana da Silva Padilha[2], Ausdinir Danilo Bortolozo[1], Wislei Riuper Osório[3], Sâmia Morato Faria[4]

Lightweight materials with good mechanical properties are alternatives to reduce the mass and energy used in motor vehicles. Components cast with A356 and A413 alloys are used for this purpose. The production of these alloys, can improve the mechanical properties, but on the other hand, it can affect the corrosion resistance due to the formation of second phase. By inserting alloys into saline solutions, the corrosion develops, forming the corrosion products. Thus, this study aims to analyze the corrosion rate in for A356 and A413 alloys in the presence and absence of light (ASTM G1, 2003). A mixture alcohol: acetone (1:1, v/v) was used to drying. An analytical electronic balance (10^{-4}g) to obtain the weight values of the proposed alloys was used. In order to remove the corrosion products, all the samples passed through cleaning solutions (ASTM G1, 2003). After each one of the immersion periods by 6042 h, in order to evaluate the sample degradation (weight change, diameter and thickness), the samples were taken out and the cleaning was carried out. The pH analyses of corrosive media were also followed.Results show that samples (A413) with incidence of light suffered a mass reduction of ~42% (light: $3.1.10^{-6}$g/h; without light: $1.8.10^{-6}$g/h) in relation to those in the light absence. To understand the shape and corrosion products in alloys A356 and A413,the same behavior was not observed, but it was noted that after 3400 h, the Al particles became more defined in relation to A356. This may be related to the amount of Si that influenced the corrosive process due to the greater formation of the galvanic couple,in addition to the porosity of the material that can increase the surface area for NaCl to act.The pH results of the solutions show the most acidified medium n the light incidence(5.30) in relation to the absence of light (6.40).

e-mail: walter.leandro@ufpe.br

The use of coatings is one of the most widespread techniques to combat the corrosion process, as it delays the access of the electrolyte to the substrate [1,2]. Nickel-based coatings have been a commonly used strategy, due to the anticorrosive properties, high hardness and good wear resistance of this type of material. Nickel plating obtained by electroplating is an advantageous option due to its fast execution and relatively low operational cost [3]. Phosphatization is a pretreatment that not only improves the adhesion of coatings to the substrate by forming a porous layer of inorganic precipitates, but also retards corrosion due to their non-conductive nature [1]. The objective of this work is to evaluate the influence of phosphatization as a pretreatment in the electrodeposition of nickel on ASTM A36 steel substrates. Four conditions were analyzed: uncoated steel (E00), phosphatized steel (E00F), nickel-coated steel (E10), and phosphatized and nickel-coated steel (E10F). Morphological and chemical characterizations were performed using SEM and EDS. The anticorrosive behavior was analyzed using EIS and potentiodynamic polarization. Wear resistance was analyzed by means of a tribometer. The phosphatization process influenced the resulting morphologies, leading to an increase in pointed lamellar structures on the surface, as well as an increase in anticorrosive protection and wear resistance, with the bests results observed in the phosphatized and nickel-coated steel sample.

e-mail: jorgecsilvaf@gmail.com

The aim of this work was to prepare sintered Nd-Fe-B permanent magnets, following the traditional powder metallurgy route, using reduced graphene oxide (rGO) in the mechanical milling process. Also, it was to study the effect of rGO addition on the magnetic properties of the as-prepared materials. rGO acts as a lubricant and effective milling medium, preventing agglomeration, welding of the particles, and oxidation of the material. The structure and morphology of the composite powders were characterized by X-ray diffraction, Raman spectroscopy, and transmission electron microscopy. The magnetic properties of sintered magnets were characterized using a permeameter. The highest values of remanence (Br) and intrinsic coercivity (iHc) values were obtained for the sintered magnet using 0.02 wt% rGO addition, Br = 1.1 T, and iHc = 764.0 kAm-1

Influences of the Warm-Rolling Process in the Microstructure and Mechanical Properties of the CrMnFeCoNi High Entropy Alloy

e-mail: carolgoncalves92@hotmail.com

The influence of warm-rolling on the microstructure and mechanical properties of the FCC equiatomic CrMnFeCoNi high entropy alloy (HEA) was investigated. The HEA was warm-rolled to 76% and 90% reduction in thickness at 773 K. The warm-rolled HEA resulted in a lamellar microstructure, notably coarser than the cold-rolled material found in literature [1,2]. The difference in microstructure could be a consequence of the dynamic annihilationof dislocations during deformation. In addition, nano-twins were introduced during warm-rolling process. The chemical fluctuation in the HEA warm-rolled indicated the formation of second phases. The HEA warm-rolled in different thickness reductions resulted in a great combination of strength-ductility in which the high strength is due to a reduction in the free path of dislocation by nano-twins inside the grains and the ductility attributed to the recovery process during deformation. In summary, the present results indicate that the warm-rolling could be effectively used as a thermo-mechanical route for tailoring microstructure and mechanical properties of the CrMnFeCoNi alloy and possibly in other single-phase FCC HEAs.

Beta metastable Ti alloys are potentially interesting as structural biomaterials. When it is solution heat-treated above the β-transus temperature and rapidly cooled, it is possible to obtain microstructures constituted by the β phase (bcc) with a low elastic modulus, which is essential to avoid the stress-shielding phenomenon. When aged, it can present the α phase (hcp) precipitation into a β phase matrix, which increases the mechanical strength of this material. By controlling the aging process, it is feasible to obtain components with low elastic modulus and high mechanical strength. For example, it is possible to adjust the elastic modulus to values between 60 GPa and 110 GPa and yield strength from 500 to 1000 MPa. When this precipitation is based on heterogeneous nucleation assisted by the ω phase, the precipitation is intragranular. However, aging can also produce intergranular precipitation assisted by grain boundaries. In this context, the objective of this work was to investigate the aging heat treatment conditions of the Ti-19Nb-2.5Fe-6Sn alloy (wt%) and explore the competition between intragranular and intergranular precipitation. The α phase precipitation was investigated through differential scanning calorimetry, X-ray diffraction, and scanning electron microscopy. The effect of intergranular/intergranular precipitation on mechanical behavior was evaluated. The results showed that the aging temperatures are essential in obtaining intragranular precipitation of the fine and dispersed α phase in the β phase matrix. e-mail: jaderson.leal@estudante.ufscar.br

Due to the high toxicity of lead, the electronic components industry has developed new lead-free alloys, which has become a topic of great scientific and technological interest [1]. The Sn-Bi alloys are considered good candidates in order to replace Sn-Pb alloys in soldering operations [2]. However, either the mechanical properties, or the control growth of the interfacial reaction layer must be improved. The addition of In has shown good results for applications in electronic connections using low melting point alloys based on Sn [3]. In this work the influence of In on the solidification path, microstructure, contact angle, tensile properties, and interfacial features of a Sn-40%Bi alloy was studied. CALPHAD calculations, differential scanning calorimetry, scanning electron microscopy, x-ray diffraction, wettability and tensile testing were performed. The microstructures were composed of Sn-rich matrices with Sn-Bi and BiIn-Bi constituents. Significant sensitivity of the microstructural scale to the solidification cooling rate was observed by employing different processing conditions. Because of the relatively high BiIn fraction on the microstructure, a limited elongation of approximately 7% was achieved, with an ultimate tensile strength of 65 MPa. The Cu6(Sn, In)5 intermetallic phase formed on the reaction film for the Sn-Bi-In/Cu interface under all tested conditions, including as-soldered and aged at 100°C and 120°C for 120 h, 240 h, and 360 h. Wetting angles for the ternary Sn-Bi-In alloy were maintained at approximately 20°, which is smaller than usual for the binary Sn-Bi alloys. The new phase, Cu6(Sn, In)5, produced instead of Cu6Sn5, showed a lower growth ratethan that observed in In-free couples.

Low-cost metallic glasses with high performance in corrosion and wear resistance from ferrous alloys and commercial elements.

Caio Lucas Gueiros Pedrosa Martins[1], Guilherme Yuuki Koga[2], Claudemiro Bolfarini[2],
Claudio S. Kiminami[2], Walter Botta[2]

e-mail: caiogpm10@gmail.com

Metallic glasses offer a unique combination of properties, including high mechanical strength, corrosion resistance, and wear resistance [1,2]. However, research on alloys containing a glass phase is mostly carried out using high-purity precursors, which are costly. Therefore, there is an interest in developing metallic glasses from more accessible raw materials, such as ferrous alloys. This study aims to develop a high-corrosion- and wear-resistant metallic glass from pig iron, a low-value-added ferrous alloy with a high impurity content. Initially, a pig iron-based alloy with commercial purity elements such as Cr, Fe-B, Fe-Nb, and Fe-Mo was produced in an electric arc furnace and then processed through rapid solidification by melt-spinning. Subsequently, the obtained alloy was characterized using X-ray diffraction (XRD), differential scanning calorimetry (DSC), and transmission electron microscopy (TEM) to evaluate the formation of the glass phase, as well as electrochemical analysis. The results showed the formation of a glass ribbon with excellent corrosion and wear resistance. These findings are significant for the development of low-cost metallic glasses, which have a broad range of applications in advanced technology.

e-mail: fabricia.gonzaga@itec.ufpa.br

Modern industry has opted for the use of aluminum alloys in various engineering components due to its low-density combining lightness and high strength property. The aerospace and automotive sectors have therefore sought the machining process of these alloys as a more favorable finishing operation to obtain better dimensional accuracy and ideal surface finish in the field of parts manufacturing [1]. The removal of a material through contact between the cutting tool and the part generates a large expenditure of energy in the form of heat due to friction and plastic deformation [2]. Several tests can be carried out to assess the quality of the machining process, such as necking tests on the lathe with a cutting tool. The evaluation of these cutting temperatures allows them to be later controlled by knowing the cutting conditions (tool material, process parameters and environment) and even the alloy preparation process (with the control of thermal and microstructural parameters of solidification), promoting analysis of the impact that this heat can generate on tool life and wear mechanisms [3]. Hence, this work aims to study the cutting temperature obtained through the infrared method, during the necking process of the ternary Al-4.5%Cu-1%Mg solidified in a horizontal device. The results show a variable behavior of the heating rate during machining along the ingot. In the transition zone from columnar to equiaxed grains, there was a sharp drop in cutting temperature, suggesting that this zone has a lower hardness value.

Low hysteresis and moderate magnetostriction at low magnetic fields of FeGa alloys makes it attractive for actuator and sensing applications. The alloy with better magnetostriction contains 18.6at.% of Ga, but shows poor ductility. The addition of B on these alloys improves ductility without affecting magnetostriction. Magnetostrictive strain comes from magnetization rotation and thus is closely related to its magnetic domain patterns. The configuration and evolution of magnetic domain structure under a magnetic field are important for understanding the magnetostrictive response of materials. Magnetic force microscopy was used for the investigation of the magnetic domains of FeGa alloys. Recently was reported a significant development in FeGa alloys magnetic domain, where cellular domain structures were observed [1]. The magnetic domains of FeGa alloys with added B has not yet been explored. In this work, the magnetic domains of $Fe_{81.4}Ga_{18.6}$ and $(Fe_{81.4}Ga_{18.6})_{0.98}B_2$fabricated by arc furnace melting with Ar-controlled atmosphere are analyzed. The magnetic properties of these alloys were previously reported [2]. For the analysis, the microstructural characterization of the samples is performed using a scanning electron microscopy. The local evolution of magnetic domain structures in FeGa e FeGaB under variable magnetic fields (0-300 mT) is characterized via magnetic force microscopy and magneto-optical Kerr microscopy.

Magnetic response of cobalt oxide ultra thin films

Fernando Alvarez Asencio[1], Ricardo Henriquez[1], Claudio A. González-Fuentes[2]

[1]Universidad Técnica Federico Santa María (*Physics*) , [2]Universidad de Santiago de Chile (*Fisica*)

e-mail: falvarezase@gmail.com

Cobalt thin films were evaporated in a high vacuum system on mica and SiO2 substrates. The film thicknesses were varied between 1 and 15 nm. The samples were oxidized at RT, 100ºC, 150ºC and 200ºC, at ambient conditions by 1 hours. Raman spectroscopy and ellipsometry were performed in all samples. The characteristic Raman shift peaks corresponding to CoO (200, 480 and 690 cm-1) appear clearly in samples oxidized at RT and 100 ºC; they can be weakly identified in those oxidized at 150ºC; and they disappear in thefilms oxidized at 200 ºC. On the other hand, the values obtained from the ellipsometry wereconsistent with a refractive index of CoO. The magnetic characterization of the samples wasperformed, determining the hysteresis loop of all samples. Results shows no ferromagneticresponse from 5 nm down. From 10 nm thick to up, ferromagnetic signal is observed. Thebehavior is maximized for samples with 10 nm thickness, reaching a saturation field of 1E-7Oe and magnetic coercivity of 33, these values increase as the oxidation temperature and thickness increase.

Methodology for developing a model to predict CCT diagrams of O&G steels

José Roberto Souza Jr.[1], Marcus Vinicius Ferreira Lemes[2], Vicente Braz da Trindade Filho[2]

[1]Vallourec Soluções Tubulares do Brasil (*Research and Development*) , [2]Vallourec Soluções Tubulares do Brasil

e-mail: joseroberto.souzaj@vallourec.com

For production of high end seamless steel pipes, which are obtained by quenching and tempering treatments, the continuous cooling transformation (CCT) diagram is a very important tool to comprehend the phase transformation and to predict the final microstructure of the steels. However, it is difficult to obtain these diagrams for every steel since a high experimental effort is necessary. This study presents a methodology of modelling using linear regression method to determine the relationship between the chemical composition of steels and the austenite transformation kinetics during the continuous cooling. The developed model makes possible to calculate the CCT diagram for steels with a known chemical composition and to analyze the influence of specific elements on the transformation curves of austenite. The methodology was developed first on the basis of information available in literature consisting of equations used for constructional steels and then it was adapted for Oil and Gas steels using experimental data obtained by dilatometry tests. The model presented in this paper is a useful tool in selection of the chemical composition of steels for heat treatment of pipes for O&G applications.

MICROSTRUCTURAL ANALYSIS AND THERMAL PARAMETER CHARACTERIZATION OF DIRECTED SOLIDIFICATION OF AL-3.2BI-0.5ZN ALLOY UNDER TRANSIENT HEAT EXTRACTION REGIME.

Monotetic Al-based alloys present microstructural characteristics that make them notable for specific applications, such as in tribological systems. The binary system Al-Bi has been the subject of important investigations from the point of view of phase transformations and microstructural characterization. On the other hand, little is known about the effect caused on the microstructure - phases formed and morphology - by the addition of a new Al-Bi-X alloying element. In this investigation, 0.5% by mass of Zn was added to the monotetic alloy Al-3.2%Bi [1]. Considering that the added element has high solubility in the α-Al phase, it was expected that the microstructural morphology of the ternary alloy would remain the same as that of the binary monotetic. The alloy investigated in this work was directionally solidified in order to allow the obtainment of wide ranges of solidification thermal parameters and interphase spacings [2]. Optical micrographic analysis (OM) shows a uniform aspect matrix, without the presence of relevant boundaries, and globules with Bi presence, besides empty cavities, probably due to Bi detachment during grinding and/or polishing stages. The images recorded through the Scanning Electron Microscope (SEM) with Energy Dispersive System (EDS) module allowed confirming that the microstructure of the ternary alloy Al-3.2%Bi-0.5%Zn corresponds to the α-Al matrix, rich in Al and Zn, with planar morphology, and Bi globules dispersed along the primary phase.

e-mail: ana.nascimento.131@ufrn.edu.br

Stainless steel 309L is used in the oil and gas industries to coat pipelines and equipment, standing out for having a low cost and good anti-corrosion properties, presenting in its composition high concentrations of chromium, nickel and low percentage of carbon, which increases weldability and the corrosion resistance of cladding components. For the production of the claddings, the MAG (Metal Active Gas) welding process was used and as a result, Partially Diluted Zones (PDZ) were formed - which present microstructural variations depending on the process parameters used - these, contributing and significantly influencing the final mechanical-metallurgical properties of the claddings [1]. In order to know and optimize the mechanical and anti-corrosion properties, it is extremely importantto know the microstructural aspects in order to understand the metallurgical transformations in the Bonding Zone (BZ) and, in this way, to investigate the influence of welding parameters on the formation of PDZs. With this, a microstructural evaluation of the dissimilar claddings was carried out via Electron Backscatter Diffraction (EBSD), with the objective of performing the microstructural mapping and understanding the influence of the welding parameters on the microstructure of these regions. In addition to the EBSD, the technique of Energy Dispersive Spectroscopy (EDS) and microhardness were used, in order to correlate the microstructural and chemical analyses with the mechanical properties in the cross-sectional region of the cladding, specifically in the PDZs.

Microstructural evolution of Al-Al3Ti-based alloy prepared by sintering of commercial powders

João Paulo de Oliveira Paschoal[1], André Victor Rodrigues Dantas[1], Daimer Velasques Tamayo[1], Juliano Soyama[2]

[1]Universidade Estadual de Campinas, [2]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*)

e-mail: joaooliveirapaschoal@gmail.com

The use of less expensive powders for the synthesis of materials results in a lower final product price, turning them more attractive for industrial applications. However, the quality of raw materials including impurities in their chemical composition, as well as the particle size distribution and morphology might influence the mechanical properties. In this context, the use of low-cost commercial-grade powders still requires investigation for the processing of Al-Al3Ti-based alloys. Therefore, this work aimed at evaluating the processability, microstructural evolution, and hardness of an Al-Al3Ti-based alloy prepared via Powder Metallurgy of commercial powders. Two powder mixtures with different powder particle sizes; both with approximately 26 wt.% of Ti; were uniaxially cold-pressed at 200 MPa, and sintered at 700°C for 30, 90, 120, and 240 minutes. In both cases, after 240 minutes of sintering, a homogenous microstructure was observed, with low porosity, and significantly refined and dispersed intermetallics.

Al-Mg-Sc alloys can be applied in different industrial sectors due to the relatively high specific strength and adequate resistance to corrosion. The purpose of this work is to process Al-3, -5 and -10wt.% Mg-0.1wt.% Sc alloys (commercially known as Scalmalloy) both by upward directional solidification (DS) and by laser surface remelting (LSR), and, after that, to evaluate the microstructures, phase morphologies and hardness. The two solidification techniques applied are complementary and allow not only the mapping of the microstructure as a function of thermal solidification parameters, but also the analysis of samples under extreme conditions of solidification when processed by LSR. LSR is an effective way to increase the hardness of Al alloys by refining the microstructure of the surface layer. Surface remelting was performed using an Yb:fiber laser under Argon protection. Four (4) laser heat inputs were examined for alloy substrates extracted from the DS samples and corresponding to the same solidification rate (2°C/s): 1.7, 2.5, 5.0 and 10 J/mm. Thermodynamic simulations (CALPHAD), optical microscopy, hardness, X-ray Diffraction and SEM analyses were employed to investigate the phases formed. The upward DS caused a microstructural and morphological variety in the three Al-Mg-Sc alloys with presence of cells and dendritic morphologies. Thermodynamic simulations indicated the formation of the $Mg_2Al_3$and Al_3Sc phases for the three DS compositions. For the lowest heat inputs (1.7 and 2.5 J/mm) Vickers hardness of the Al-3% and -5%Mg(-Sc) LSRed samples were increased approximately 15-20% as compared to the DS samples. However, in the case of the Al-10%Mg-0.1Sc alloy treated at 1.7 J/mm only a small hardness increase was observed from 114 HV (DS) to 118 HV (LSR).

Microstructure and hardness of warm and cold rolled Ti/Nb-IF steel

Felipe Azevedo de Carvalho[1], Cristiane Maria Basto Bacaltchuk[1], Hector Reynaldo Meneses Costa[1], Gilberto Alexandre Castello Branco[1]

[1]Centro Federal de Educação Tecnológica Celso Suckow da Fonseca

e-mail: felipe.azevedo.carvalho@gmail.com

Interstitial free (IF) steel is well-known by its excellent deep drawing performance. Variations in the thermomechanical processing can have strong effect on microstructure and mechanical properties of IF steels [1,2,3]. In order to investigate the effect of deformation temperature on microstructure and hardness of Ti/Nb-IF steel, two distinct deformation processes were carried out. The first strip (WR) was 80% warm rolled and the second strip (WCR) was 40% warm rolled and 40% cold rolled. Both strips were annealed at 900°C for 120 seconds. The annealed WR and WCR samples exhibited recrystallized microstructures with similar mean grain size values, 98 μm and 91 μm, respectively. According to these results, 40% cold deformation after warm deformation has shown not to be able to significantly increase dislocation density and deformation energy to promote nucleation of a higher number of new grains. The microhardnesses for the two annealled samples were also similar, about 83 HV. The texture results however, showed a positive effect of cold deformation in the previously warm rolled sample. After warm rolling, Goss texture component was developed but neither alfa nor gamma fiber were. On the other hand, warm rolling followed by cold rolling resulted in an intensification of the alfa fiber texture, which was beneficial for the further development of gamma fiber texture after annealing processing.

Microstructure and properties of Al-3, -5 and -10 wt. % Mg-0.1wt. % Sc alloys solidified at different cooling rates

Anderson Thadeu Nunes[1], Guilherme Lisboa de Gouveia[1], José Spinelli[1] [1]Federal

University of Sao Carlos (*DEMa*)

e-mail: atnunes@estudante.ufscar.br

Aluminum alloys are very employed in engineering devices like those from aeronautical, aerospace industry and microelectronic, among others, due to combination of low density, mechanical strength and adequate corrosion resistance. It is well Known that the microstructure of these alloys depends on both the alloy composition and the processing conditions, so more in-depth studies regarding their solidification still need to be carried out. Then, the search for alloys with higher specific strength is justified from environmental and economic point of views. The aim of this work is to investigate the influence of cooling rates on the phase morphology, phase transformation and mechanical properties of three ternary Al-3, -5 and -10wt.% Mg-0.1wt.% Sc alloys, whose composition covers the spectrum of alloys known commercially as Scalmalloy. These alloys were processed by upward directional solidification whose a wide range of cooling rates results on the formation of a microstructural variety along the longitudinal cooling direction and hence different tensile properties.The upward directional solidification process caused a microstructural and morphological variety in the three Al-Mg-Sc alloys. Cells and dendritic morphologies were observed by optical microscopy. Thermodynamic simulations (CALPHAD Method) indicated formation of the beta phase intermetallic (Mg_2Al_3) and Al_3Sc phase for the three compositions. Superficial residual marks observed in the SEM analyses indicated indirectly the presence of Mg_2Al_3. Thermal analysis (DSC) confirmed the beginning features of solidification for each investigated alloy. The observed improvement in tensile properties can be associated with microstructural transformations and the mechanism of increased resistance by solid solution (Al-Mg) together with the formation of the Al_3Sc precipitates, whose detection is still a work in progress.

e-mail: maricordeiroeq@gmail.com

Among the waste of electrical and electronic equipment (WEEE), the printed circuit boards (PCB) present the highest valuable metals' concentration - Au, Ag, Cu, and Sn. Such metalscan be recovered in a process known as urban mining [1]. In this scenario, the present work studied selective Cu extraction from microcomputer PCB from two different particle s by hydrometallurgical technique. The samples were ground and fractionated. They were divided into gross (0.71 to 2.84 mm) and fine fraction (0.71 mm). The Cu extraction was performed by leaching processes - 2 M H_2SO_4 added $H_2O_2$30% (p./v.), and the solid/liquid ratio was 1/10. Each leaching process was performed under magnetic stirring (200 rpm) for 1 h at room temperature (30°C). After the leaching process, the solution was filtered and stored. Successive washes with distilled water were also performed and the filtrate was stored. Both leach and wash water solutions were analyzed for the presence of Cu by inductively coupled plasma-optical emission spectroscopy (ICP-OES). The total Cu presentin the fine and gross samples was obtained by analyzing the final solution also by ICP-OESafter the acid digestion process (3/4 HCl and 1/4 HNO_3, both in analytical grade). The extraction percentage (EP) for fine and gross fractions reached (69±2) % and (44±1) %, respectively. As expected, the extraction of Cu in smaller particle fractions tended to increase the EP due to the enhanced surface contact area of the solid with the leach solution. Therefore, aiming for greater EP, it is recommended that prior milling to micronize the PCB.

e-mail: p.mengarda@lactec.com.br

The production of oil and gas in deep waters requires the use of highly sophisticated equipment, and efficient forms of protection to ensure its integrity. Damage to the outer layer of flexible pipes can lead to marine electrolyte permeation into the metallic (annular) region, as well as water vapor along with gases such as H2S and CO2 can also permeate from the internal fluid toward the annulus. Under any circumstances, flooding of the annular region results in a shorter operational life due to corrosion-related failure mechanisms [1], and the effectiveness of cathodic protection over these structures becomes essential. There is still no consensus on the classification criteria regarding the permeability of cathodic protection along flexible pipes since there is currently no adequate technique that mainly allows monitoring corrosion in restricted regions such as the annular section [2]. In this work, computational models were developed using the COMSOL Multiphysics® software to evaluate the range of cathodic protection in the annular region exposed to the permeation of aggressive species was evaluated. It was possible to assess the current and potential distribution at each point of the flexible pipe. A correlation between the influence of species that permeate the annular region and the effectiveness of cathodic protection was acquired, considering parameters such as solubility, particle , and diffusibility. The results allow the improvement of corrective measures to prolong the lifetime of these components.

Morphological stability of Al7Si2.5Cu alloy processed via ultrasonic melt treatment for thixoforming process application

João Paulo de Oliveira Paschoal[1], Luis Vanderlei Torres[2,1]

[1]Universidade Estadual de Campinas, [2]Instituto Federal de Educação, Ciência e Tecnologiade São Paulo

e-mail: joaooliveirapaschoal@gmail.com

Developed in the 1970s, semi-solid metal processing has received considerable interest in recent years due to advantages over manufacturing processes like casting. Furthermore, obtaining an alloy with refined microstructure before the thixoforming process is crucial, which is hampered when dealing with aluminum alloys with high silicon content. Therefore, ultrasonic melt treatment (UST) takes place as a possible solution for grain refining. Aiming to evaluate the alloy's morphological stability in the semi-solid state, the melted material was submitted to ultrasonic melt treatment for 20 seconds. After that, the ingots produced were processed via reheating heat treatment at 572°C (45% of solid fraction) for 0, 30, 90,and 210 seconds. Resulting in an average size of primary globules around 88μm, and a circularity form factor above 0.50, it is concluded that UST is an effective alternative for the thixoforming process.

NbC-reinforced Ti composites manufactured by Spark Plasma Sintering (SPS)

William de Paula Santos[1], Jean-Louis Bobet[2], Anibal de Andrade Mendes Filho[3], Sydney Ferreira Santos[1]

[1]Federal University of ABC (*CECS*) , [2]Institute of Condensed Matter Chemistry of Bordeaux, [3]Federal University of ABC

e-mail: william.santos@ufabc.edu.br

Over the years, there is a growing interest on the use of Ti composites for several technological applications, particularly in the aerospace, automotive, and biomedical device industries. To enhance the mechanical properties of the Ti matrix a variety of reinforcements have been researched, including carbon materials, metal oxides, Kevlar, silicon carbide, and others [1]. In this investigation, the use of NbC as reinforcement was investigated. Morever, the Spark Plasma Sintering (SPS) was tested to consolidate the Ti-NbC composite samples from the mixture of Ti and NbC powders (1:1wt. ratio). Different types of powders were tested to produce these mixture: as-received NbC and Ti powders and cold-rolled Ti and NbC powders. SPS was carried out with heating up to 1000°C, and the samples were kept at this temperature for 3 and 15 min. To assess the mechanical properties and microstructures, microhardness testing and scanning electron microscopy were employed. Samples synthed by SPS showed good consolidation and distribution of NbC particles. Greater microstructural homogeneity was observed for the samples produced with as-received powders and also for the samples in which both NbC and Ti powders were laminated before sintering (SPS with plateau at 1000°C for 3 min). In contrast, in the samples where only one powder was laminated, elongated Ti profiles were observed. This feature was more evident for the sample with Ti:NbC ratio of 1:1. The samples also exhibit significant anisotropy between longitudinal and cross-sections, as observed from microhardness tests. These results indicates that, with adequate selection of the processing parameters, SPS is an interesting route to produce Ti-NbC composites.

e-mail: alanasjcsp@hotmail.com

During the operation of a hypersonic vehicle equipped with hypersonic airbreathing propulsion system technology operating over a wide range of flight conditions, it results in high temperatures in the aerodynamic structure causing thermal stresses and rapid ablation. In this context, it was necessary to apply smart materials on the leading edge cowl of the scramjet engine, having a variable geometry that allows the engine to adapt to the different mission profiles faced in its flight [1]. The material chosen for the present work was NiTi (nitinol) alloy, which started with an equiatomic amount of high purity powders,passing through the process of weighing and mechanical mixing in a high-energy planetarymill [2]. Presently, the powder pressing and compacting stage began and finally the reactionsintering process via laser in vacuum. Analysis by secondary ion mass spectrometry revealed that there was variation of oxygen in the layers, regardless of the process parameters, and X-ray diffraction showed the formation of the Ni-Ti system phases and theoxides ($Ni_xTi_yO_w$and Ti_xO_y). Optical microscopy revealed the presence of isolated and interconnected pores of different sizes and morphologies.

As an energy carrier, Hydrogen has been studied by the capacity of be a green alternative to energy storage. Among different options of hydrogen storage and transportation, multicomponent alloys has been explored as the large compositional field of these alloys allow the control of the thermodynamic properties of the hydrogen storage. The laboratory of hydrogen in metals at DEMa/UFSCar already has a vast experience in synthesis, characterization, and evaluation of properties of these alloys. To improve the capacity of design alloys for specific applications, a first model to predict thermodynamic properties and the pressure-composition-temperature (PCT) diagram of multicomponent body-centered-alloys (BCC) has proposed by Zepon et. Al. [1]. The elements Mg, Al, Sc, Mn, Fe, Co, Cu, Zn, Mo, and Pd were incorporated into the model and their implementation in open-source code in the Python programming language was made for facilitate the utilization and diffusion of the model [2]. The modeling of systems of alloys reported in the literature were done to demonstrate the utilization of the code as an exploratory tool before the synthesis and characterization of multicomponent BCC alloys.

Oxidation of protective aluminide coatings at 1000°Cfor ϒ-TiAl alloy by pack cementation

Nelise Julien Pinto de Moura[1], Nabil Chaia[2], Carlos Angelo Nunes[1], Gilberto Carvalho Coelho[1]

[1]Escola de Engenharia de Lorena - EEL/USP, [2]Universidade Federal de Alfenas (*ICT*)

e-mail: nelise.engenharia@usp.br

Titanium alloys are very attractive for utilization in aerospace industries due to their good mechanical properties and low density (4.54 g/cm³). They are recently considered to manufacture turbine components and turbocompressors to supplement Ni-based alloys that, despite their excellent mechanical resistance, have relative high density [1]. However, Ti-based alloys have low oxidation resistance when exposed to high temperatures [2]. Thus, the present work aims to optimize conditions for the formation of titanium aluminide protective coatings on γ-TiAl substrates, with the nominal composition Ti(bal.)-43.5Al-4Nb-1Mo-0.1B (at.%), using the pack cementation technique. Depositions were carried out at 900°C for 4, 9, 16 and 25 hours in vacuum sealed silica vessels.Oxidation resistance of bare and coated substrates was investigated by means of pseudo-isothermal tests carried out at 1000°C for 300 h. Microstructural characterization of thecoatings and the oxidation products was performed by XRD, SEM and EDS. The coatings arecomposed mainly by $TiAl_3$and the mass gains for the coated specimens were six times lowercompared to the bare alloy. A protective layer of $Al_2O_3$was observed for the coated specimens because of the high Al content in the coating ~75 at.%. In contrast, oxidation products formed on the bare γ-TiAl alloy were mainly $TiO_2$and Al_2O_3, non-protective and poorly adherent.

Preparation of lanthanum acetate from a mixed rare earths concentrate

Carlos Alberto da Silva Queiroz[1,2]

[1]Instituto de Pesquisas Energéticas e Nucleares (*CCTM*) , [2]COMISSAO NACIONAL DE ENERGIA NUCLEAR

e-mail: cqueiroz@ipen.br

A simple and economical chemical process to obtaining lanthanum acetate of high purity was studied. The raw material in the form of mixed rare earths carbonate 24% $La2O3$ comes from commercial Brazilian monazite. It is used the technique of strong cationic exchange resin, proper to water treatment to the lanthanum''s fractionation and it is achieved a purity of 99.9% $La2O3$ and yield greater than or equal 90%, with the elution of rare earths by EDTA solution at pH 4.0. The complex of EDTA-La is transformed in $La2O3$, subsequently the lanthanum oxide is dissolved in acetic acid to obtain the cerium acetate. The solid salt then is characterized via chemical analysis, thermal analysis, X ray diffraction, infrared spectroscopy and mass spectrometry to certify the lanthanum acetate purity. The analytical data collected allowed to conclude that the stechiometric formula for the compound is $La (CH3COO)3.1.5 H2O$.

e-mail: flaviofavaro@estudante.ufscar.br

Multicomponent alloys represent a new class of materials that are characterized by not having a single principal element but rather being formed of concentrated solid solutions [1]. These alloys have been the focus of numerous studies due to their unique properties. In this work, we focus on the CrCoNi system, which is an example of an alloy that combines strength, ductility, and corrosion resistance. Our objective was to produce a duplex alloy of this system by choosing a composition predicted by CALPHAD thermodynamic calculations. The resulting alloy was then characterized using various methods, including optical microscopy, electron scanning microscopy, EDS, Vickers microhardness tests, and x-ray diffraction. Our experiments showed that the alloy had both FCC and BCC structures, and that the chemical compositions of these structures were consistent with the values predicted by the thermodynamic calculations. Additionally, we analyzed the effects of cold work on the material. One of the main findings of this work was the absence of the sigma phase in the alloy, which was also consistent with the predictions made by the CALPHAD method.

Multi-principal element alloys (MPEAs) represent a new class of materials which do not have a major alloying element, being composed of concentrated solid solutions of several different alloying elements [1]. Among these alloys, numerous compositions of the CrCoNi system stand out for having excellent properties, such as strength, ductility and corrosionresistance [2].The development of these alloys has given focus to the search of compositionsthat form face-centered cubic (FCC) structures. However, there are studies that indicate that duplex alloys with microstructures composed of both BCC and FCC phases are capableof presenting excellent mechanical Properties [3]. In this work, an ingot of an MPEA withthe composition Cr44Co35Ni16Al5 will be manufactured. This promising composition for theformation of a duplex structure was chosen based on thermodynamic analyzes and calculations carried out with the Thermo-Calc® software. The ingot of this alloy will bemanufactured through directional solidification using a Bridgman furnace. The objectives ofthis work are: i) the development of the directional solidification process in transient heat extraction regime of the MPEA Cr44Co35Ni16Al5; ii) Microstructural analysis using opticalmicroscopy and scanning electron microscopy (SEM), correlating with cooling rate; and iii)Evaluation of mechanical and corrosion properties resulting from samples solidified underdifferent conditions of cooling rates.

Production and Characterization of Duplex High Entropy Alloys of the CrCoNiAl System with High Crand Co

Gabriel Italiano Leal[1], Pedro Henrique Fernandes Oliveira[1], Francisco Gil Coury[2]

[1]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais (DEMa)*) ,
[2]Univerdade Federal de São Carlos (*Engenharia de Materiais*)

e-mail: gabriel.leal@estudante.ufscar.br

This research presents a study about some high entropy alloys (HEAs) or multi-principal element alloys (MPEAs). Considering the HEAs already produced, the compositions of the CrCoNi system (mainly the equiatomic composition Cr33Co33Ni33) stand out for presenting promising properties with a good combination between resistance and ductility [1].

Most of the studied HEAs are formed of face centered cubic (FCC) structures, but researches have shown that duplex HEAs, also formed by body centered cubic (BCC) phase, have promising mechanical properties [2]. However, little is known about these alloys, because most of the studied alloys containing the BCC phase present the sigma or B2 phase, often presenting brittle and hard behavior, [3], decreasing the interest in studying these compositions.

Thermodynamic calculations were performed to choose four non-equiatomic compositions with high Cr and Co to form duplex structures (FCC/BCC) in CrCoNi and CrCoNiAl systems. Adding aluminum, the duplex field increases on the diagrams, because this element stabilizes the BCC phase. Therefore, it is also possible to add more Co to obtain greater ductility in the alloys.

The alloys were characterized in as cast, homogenized, cold rolled and recrystallized conditions by optical microscopy, X-ray diffraction (XRD) and Vickers micro hardness. Some of the results obtained present dual phase eutectic alloys, another alloy with just one phase, and other results that will help to evaluate the potential and the properties of duplex alloys of the present systems.

e-mail: carolinescc13@gmail.com

Multi-principal element alloys (MPEAs) offer great potential for developing new materials with unique properties that can be tailored to specific applications. However, selecting the right composition can be challenging due to the vastness of the possibilities. To overcome this challenge, the genetic algorithm approach is an effective tool that can generate new alloy families through cross-over and mutation in each new generation, bringing their properties closer to the desired characteristics [1]. A genetic algorithm was created and employed to select two face-centered cubic single-phase multielement alloys based on the parameters VEC and phi while targeting high values of the Hall-Petch constant [2] and the critical resolved shear stress [3]. Their structure was confirmed using thermodynamic calculations via the CALPHAD method, and the alloys were produced using high-purity elements via arc melting. To assess the properties of the selected alloys, Vickers microhardness, optical and scanning electron microscopy, and X-ray diffraction with synchrotron radiation were employed, including in-situ tensile tests. The XRD pattern was also used to calculate the material pair distribution function. These findings were used to validate the genetic algorithm predictions. Overall, the potential of the genetic algorithm is discussed as an approach in the selection of novel materials.

e-mail: viniciusveiga12@hotmail.com

Researchers have shown that the Covid-19 pandemic has accelerated several issues, driving the decarbonization of the energy sector. Among these changes, the increased demand for lithium-ion batteries is a highlight, both for use in vehicles and in energy storage for domestic and industrial purposes. Studies show that this continuous increase in demand for batteries can bring environmental problems in the medium term, caused by the accumulation of batteries that arrive at the end of their useful life and are not recycled or recovered [1]. Lithium-ion batteries are rich sources of metals with high commercial value, such as cobalt, lithium, nickel, aluminum and copper. In this context, this research aimed to recover the cobalt contained in lithium-ion batteries, used and discarded, for the synthesis of a cobalt catalyst in the production of biodiesel. The recovery of cobalt from used batteries went through the steps of dismantling, separating the cathode, evaporating the solvents and scraping with a spatula to remove the deposited material, LiCoO2. For the synthesis of the cobalt catalyst, the material underwent acid leaching and subsequent evaporation. Finally, the catalyst was characterized by x-ray diffraction (XRD) and x-ray fluorescence. Biodiesel synthesis was carried out by the transesterification reaction of residual frying oil with methanol [2]. A full factorial design of experiments 22 + P.C. made it possible to obtain the appropriate amounts of methanol and catalyst to be used to maximize the yield of the reaction. Yields greater than 80% were obtained using a methanol/oil molar ratio of 6 and catalyst contents of 1%, demonstrating the effectiveness of the recovered cobalt catalyst for the evaluated reaction.

Relaxation and crystal nucleation interplay in supercooled germanium and water

Azat Tipeev[1], Edgar Dutra Zanotto[1]

[1]Federal University of Sao Carlos (*Department of Materials Engineering*)

e-mail: azattipeev@gmail.com

A well-designed study of the relationship between crystal nucleation and relaxation processes in supercooled liquids could clarify some critical issues in condensed matter science. Using molecular dynamics simulations, we obtained the self-diffusion coefficient, $D(T)$, and the shear viscosity, $\eta(T)$, in supercooled germanium and water, both described viaa Stillinger-Weber potential. Then, three relaxation times were determined 30 % below the equilibrium melting temperature, via i) the shear viscosity, τ_η; ii) the incoherent intermediate scattering function, τ_α; and iii) the self-diffusion coefficient, τ_D. We found that $\tau_\alpha(T) \approx \tau_D(T)$ and $\tau_\eta(T) < \tau_\alpha(T)$, corroborating the findings of recent experimental and computational studies. The birth times of the first critical crystal nucleus at steady-state conditions, $\tau_1(T)$, were obtained both from the seeded and unseeded crystallization data as well as from the Classical Nucleation Theory for different sample sizes. A relevant finding is that the $\tau_\alpha(T)$ and $\tau_1(T)$ curves indeed cross over for germanium and water, confirming the existence of a kinetic spinodal T_{KS} for both liquids. Finally, we demonstrate that if the Kauzmann temperature T_K existed, it would be located well below the T_K; hence, crystallization would intervene in the cooling path before these supercooled liquids could reach T_K, thus averting the Kauzmann entropy paradox.

Research progress of transformation products of theZr-rich BCC phase of the Al-V-Zr system

Caio Simão de Barros[1], Denis Felipe de Barros[1], Carlos Angelo Nunes[1], Gilberto Carvalho Coelho[1]

[1]Escola de Engenharia de Lorena - Universidade de São Paulo

e-mail: caio.simao.barros@usp.br

High entropy alloys containing Al and refractory metals are promising structural materials for aeronautical applications, complementary to Ni-based superalloys. Conceptually, these alloys are preferably composed of at least five metallic elements with concentrations between 5-35 at%. [1]. The knowledge about the phase relations in the Al-V-Zr system corresponds to an important contribution for the development of these alloys, especially for works related to the development of thermodynamic databases. In the present work, the transformation products, during cooling, of the (Zr)-BCC phase, stable in the Al-V-Zr system at temperatures above 800ºC, are being experimentally investigated. Arc-melted samples were heat treated at 1100°C, for 10 days under vacuum, quenched in water, and microstructurally characterized using SEM/EDS and XRD. The results obtained confirm the non-existence of the (Zr)-BCC phase, after quenching, being replaced by the (Zr)-HCP phase, and other products. There are indications of transformations occurring in the solid state (due to the very small size of the precipitates) in the micrographs of all samples. The present results indicate that the accompanying (Zr)-HCP products are either Zr2Al or ZrV2, depending on the chemical composition of the alloy. To investigate in more detail and assert what these products are, microstructural characterizations via EBSD are planned. The results to be obtained may lead to a more precise knowledge of the phase relations in the Zr-rich corner of the Al-V-Zr system, elucidating unanswered questions from previous studies by the research group of which the authors are members.

In the country process of economic development, a driving factor is the development and expansion of the energy sector. Thinking about that, the sustainable production of clean energy has been the focus of several countries. Brazil differs from the world average because its energy matrix is primordially constituted through hydroelectric plants. However, hydroelectric plants are susceptible to the rain seasons. In this context, a diversified energy matrix can minimize the risk of a water crisis affecting the country's development. Wind and solar energy production can be a solution for this problem. The wind electric power generation represents 10,6% and solar electric power is around 2,5% in the Brazil energetic matrix. Increasing the installation of solar collectors in the industrial sector, in the commercial sector and even in residential areas may be a solution to become the Brazilian energetic matrix more diversified. An essential material for the development of solar collectors is the aluminum. Its applicability ranges from structures for fixing solar panels to the box and tubes of heliothermic collectors. Therefore, the research project in question aims to develop aluminum and aluminum alloys through the casting process from recyclable materials for application in solar collectors. The aluminum alloys will be characterized regarding the physical-chemical, corrosion resistance, tribological and mechanical properties of the final goods. The project also aims at the production of technological and scientific knowledge and its dissemination through a partnership that may be signed between teaching and research institutions, CETENS-UFRB and PROCIMM-UESC.

Spectroscopic and Morphological Characterization of MWCNTs/Ti6Al4V/CaF$_2$-Based Flux for Tubular Arc Welding Electrode

e-mail: paulafabiolapp@gmail.com

Titanium carbide-based weld coatings are attractive due to their wear resistance. However, the structural and electronic interactions of the flux components of electrodes affect arc stability and the weld surface [1]. Accordingly, this work presents the spectroscopic and morphological characterization of a nanostructured flux that could be used in tubular arc welding electrodes. The flux was produced by mixing multiwalled carbon nanotubes/titanium alloy Ti6Al4V/calcium fluoride (MWCNTs/Ti6Al4V/CaF$_2$), with a mass ratio of 1:40:4, for 1 hour at 30 rpm, using the mechanically allowed method. Scanning electron microscopy results revealed MWCNTs agglomeration around the CaF$_2$crystals and the lamellar microstructures of the Ti6Al4V alpha (α) phase. Based on the X-ray diffraction (XDR) analysis (each component) were identified the following Bragg''s plans: a) MWCNTs (002); b) α-Ti (002) and (101); c) CaF$_2$(111) and (022). In the flux, the intensities of the CaF$_2$peaks highlighted, while those related to MWCNTs and α-Ti reduced. Moreover, the FWHM of MWCNTs (002) and α-Ti (002) increased about by 4% and 39%, respectively, evidencing amorphization by the mixing process, as opposed to the behavior observed for CaF$_2$. The Raman spectrum of the flux showed characteristic bands of CaF$_2$and MWCNTs, where an apparent increase in the degree of amorphous carbon was observed compared to the MWCNTs as received, in accordance with the XRD results. In addition, redshifts in the G and G'' bands suggest microdeformations in the crystal lattices of the inner and outer tubes of the MWCNTs, as well as CaF$_2$-induced n-type doping, which may result in improvements in welding arc stability.

e-mail: denilsonaguiar@utfpr.edu.br

Phase transformations in austenitic stainless steels have been widely studied due to their technological importance. Due to the instability of the austenitic microstructure, it is subject to transforming into martensite during straining processes, which leads to the hardening of these steels. The chemical composition of austenite, the type of straining process, and the straining rate and temperature influence the phase transformation. The TRIP effect (Transformation Induced Plasticity) is much studied, as there is an increase in mechanical strength without significant loss of ductility. The TRIP effect is associated with the (α')-martensite formation, which can pass through a hexagonal-type structure called (ε)-martensite, acting as an (α')-martensite transformation core or nucleating directly from austenite during the straining. In this work, the mechanical behavior of AISI 304 austenitic stainless steels was evaluated by a tensile test at room and cryogenic temperatures. The evolution of (α')-martensite transformation was studied using optical microscopy, hardness measurements, ferritoscopy, and X-ray diffraction in the specimens tested at different strain levels. Based on the results, it is concluded that the straining increases the mechanical strength of the studied steel, and this effect is more pronounced at the cryogenic temperature. In the cryogenic condition, uniform elongation occurs at clear values positioned to the right of the curve, suggesting structural integrity for high strain levels. The increase in strength parameters without significant elongation loss in the cryogenic condition is attributed to the more considerable phase transformation of (α')-martensite from austenite during deformation in the cryogenic condition and may be associated with the TRIP effect.References:[1] I. Structural and electronic properties of BAs

ELISANGELA DA SILVA BARBOZA[1], Luis Craco[2], Teldo Anderson da Silva Pereira[2]

[1]Universidade Federal de Mato Grosso (*FÍSICA*) , [2]Universidade Federal de Mato Grosso

e-mail: elisangela@fisica.ufmt.br

In this meeting, we will present the results of our theoretical investigation regarding the structural, mechanical, and electronic properties of cubic boron arsenide (BAs) crystal performed by means of ab initio calculations based on density functional theory (DFT). In our study, BAs was subjected to hydrostatic pressures of 10%, 20%, and 30% to understand how its electronic state changes under the effect of external pressure. The aim of our study was to analyze and describe the change in electronic properties, particularly the occurrence or not of structural and electronic phase transitions at ambient pressure. In this work, all our DFT calculations were implemented using the QUANTUM EXPRESSO (Q.E) computational package. When analyzing the total energy convergence as a function of the lattice parameter, we verify that the lattice parameter is underestimated (overestimated) within the LDA approximation (GGA). The results for the bulk modulus showed good agreement with existing calculations in the literature. The comparative study of the electronic properties of the BAs systems at ambient pressure indicated agreement with the results of previous studies. In this case, the results obtained for the band structure showed that the BAs have an indirect gap between the point $\Gamma - X$ with a value close to 1.15 eV. Analyzing the pressurized BAs showed clear changes in electronic properties, particularly in the high-pressure regime, where its bandwidth is systematically reduced, revealing, in the end, the emergence of a semi-metallic state.

STUDY OF ANDIROBA CAKE POWDER AS CORROSION INHIBITOR FOR CARBON STEEL IN ACID MEDIUM

Carbon steel is widely used by various industrial sectors and civil society. This is due to characteristics such as low melting point, good weldability, good mechanical resistance and low cost. Despite these advantages, carbon steel has the inconvenience of low corrosion resistance, thus requiring a protection mechanism. Among the strategies aimed at controlling corrosion, the use of corrosion inhibitors is widely chosen. Synthetic chemical inhibitors, such as those from chromium and arsenic, were used due to their good efficiency, however, the harmful effect on the environment and human beings, led to the search for efficient and non-toxic inhibitors, resulting in natural inhibitors of corrosion. Therefore, this work aims to investigate the potential of Amazonian' s fruit residue, Andiroba cake bark, as a corrosion inhibitor on SAE 1008 carbon steel in 1 M HCl. This evaluation was performed using mass loss test and showed that efficiency 70% and 83%, when the concentration of the inhibitor was 1,11g/L and 1,44g/L, respectively. The inhibitor compounds were analyzed by Fourier transform infrared spectroscopy (FTIR) and the presence of hydroxyl groups, aromatic rings and highly electronegative atoms (N and O) often associated with natural inhibitors were observed. This study reveals that the residue obtained from Andiroba has potential to be used as inhibitor corrosion in the replacement to the synthetic inhibitors.

The use of coatings to protect mechanical components is a very common practice in industry, because they increase shelf life of components and materials, that originally would not withstand adverse conditions, such as corrosion and wear. Among the different techniques for obtaining these coatings, thermal spraying is widely used due to its relative simplicity and practicality application. The main characteristic of thermal spray coating is its heterogeneous structure, composed of pores, voids, oxides, with a very rough surface. Depending on the application, the sprayed components must pass throught a machining process to smooth the surface and improve the surface finish, which is still a challenge in the industrial sector. Thus, the objective of this work is to analyze the influence of the cutting parameters: cutting speed and feed per tooth, in the end milling of carbon steel pieces coated by thermal arc spray. For this, machining force data, cutting tool wear, surface roughness and surface hardness were analyzed in order to obtain data that characterize the machinability of this material. In addition, a microstructural analysis was carried out using an optical microscope and microhardness measurement to verify how subsurface layers were affected due to the machining process. The results indicate that the combination of higher cutting speed and lower feed per tooth (v_c= 225 m/min and f_z= 0.08 mm), among the researched conditions, presented less roughness and less tool wear. However, tool wear was very severe in all machining conditions studied, reaching or approaching end-of-life criteria normally used, in a machined length of 140 mm.

STUDY OF MATERIALS FOR CRYOGENIC ANTI- SPRINGS THAT WILL COMPOSE NEW GENERATIONS OF LASER INTERFEROMETERS FOR OBSERVING GRAVITATIONAL WAVES

Denisson Guimarães do Carmo[1,2], Odylio Denys Aguiar[3], Eduardo dos Santos Pereira[4]

[1]Universidade Estadual Paulista (*Departamento de Física e Meteorologia*) , [2]Instituto Nacional de Pesquisas Espaciais (*Divisão de Astrofísicaa*) , [3]Instituto Nacional de Pesquisas Espaciais (*Divisão de Astrofísica*) , [4]Faculdade Senai de São Paulo

e-mail: dg.carmo@unesp.br

The Laser Interferometer Gravitational Wave Observatory (LIGO) is an instrument designed to detect gravitational waves. The LIGO detections confirmed the last remaining prediction of General Relativity and ushered in a new era of gravitational wave astrophysics. In order to improve sensitivity by an additional factor of two and halve the low-frequency cutoff to 10Hz, an enhancement to the observatory, dubbed the "LIGO Voyager," is planned. This new interferometer is planned to operate at 123K temperature due to silicon''s zero coefficient of thermal expansion at this temperature. In this sense, it is necessary to adapt the components for operation in cryogenic conditions, as is the case of vibration systems and more specifically their springs. Currently, there are possible candidates to compose these springs, which have mechanical quality factors (Qm) suitable for this type of application, as is the case with the materials: Stainless Steel, Niobium, Tungsten, CuAl (6%), Molybdenum and Aluminum 5052. In order to carry out the measurements under similar operating temperature conditions of the LIGO Voyager, an experimental scheme was developed that allows subjecting the above-mentioned materials to a temperature of 77K. Thus, it was possible to observe the deflection of stainless steel under ambient and cryogenic conditions. As we cool a material, its Young''s modulus tends to increase, for practical purposes, this means that k, which represents the elastic constant in Hooke''s equation, is increased. For stainless steel, for example, it was possible to show that the cryogenic condition increased the spring constant by $1.40*10^2$ N/m.

Study of residual stresses and fracture toughness in welded and repaired joints using A516 Gr70 steel

Régis de Matos Curvelo de Barros[1], MAURICIO NEVES[2]

[1]Instituto de Pesquisas Energéticas e Nucleares (*CCTM*) , [2]Instituto de PesquisasEnergéticas e Nucleares (*CECTM*)

e-mail: barros017@hotmail.com

The properties of welded joints subjected to cyclic loading is an important subject in several áreas[1]. In this scenario, aiming to study this subject, welded joints made of ASTM A 516GR 70 steel plates, with a thickness of 30.5 mm, welded by the MAG - Metal Active Gas process (20% CO2) with the use of a K-bevel were analyzed. to allow full penetration due to the high thickness [2]. The joints were manufactured with seven welding passes on each side of the chamfer. After welding, one set was subjected to a repair pass, for remelting the surface of the bead using the TIG (Tungsten Inert Gas) process, while another set was subjected to two repair passes. This study aimed to analyze aspects of welded and repaired joints: dimensions (height and width) of the bead, behavior of the residual stress profile measured by X-ray diffraction, Vickers microhardness profile and fatigue crack nucleation with based on ASTM E466 and E606 standards. The results indicated that the greater number of repair passes decreased the compressive residual stress values in the transverse and longitudinal directions, from -350 MPa to 50 MPa. There was greater uniformity in hardness Vickers values (value between 200 and 210 HV) with the use of cord repairs. It was observed that the fracture toughness presented values of 1500 J/mm (without repair) and 900 J/mm (one pass and two repair passes), lower than that found in the material without welding (3500 J/mm). Therefore, as the repair passes were performed, the residual stresses in the weld bead tended to positive values, the hardness tended to stabilize with values of 200 HV due to the increase in the number of repair passes and the fracture toughness decreased in the welded material when compared to the values of the non-welded material. There was no significant difference in fracture toughness between repair passes.

Study of self-healing by electrical pulses with low current flow in damaged aeronautical Al alloy 7075

Juliano Augusto Medeiros[1], Mauricio Mhirdaui Peres[2], Sérgio Rodrigues Barra[2], Rubens Maribondo do Nascimento[1]

[1]Universidade Federal do Rio Grande do Norte (*PPGCEM*) , [2]Universidade Federal do Rio Grande do Norte (*Engenharia de Materiais*)

e-mail: juliano.maugus@gmail.com

High-strength aluminum alloys (7000 series) are commercially applied in strategic aeronautical structural components, but mechanical stresses during use generate microstructural defects that lead to microcracks and failure of a structure. The promotion of self-healing by applying electropulses (EPT - "Electropulsing treatment") is a recent alternative and has the advantage of promoting low heating. Microstructurally, pulsed current promotes stress relief and generates a flow of electrons with a thermal gradient in the region of microcracks that acts to compress their ends and repair them [1, 2]. Samples of a commercial sheet of alloy 7075 were subjected to tensile tests for the production of microstructural defects (grain elongation, microcavities and microcracks), being pre-deformed under different conditions (60%, 70%, 80%, 85%, 90% and 95% of rupture strain). The most severe conditions were submitted to EPT with pulses of 400 amperes, varying the current density up to 50 A/mm2 for 14 s. The microstructural characterization via SEM-FEG was carried out by correlating the damage and the mechanical behavior before and after the electropulse self-healing procedure, being discussed in terms of the effectiveness of the self-healing mechanism in the test conditions used. The applied parameters were effective in promoting partial recovery of microstructural defects with the improvement of the ductility of the samples.

e-mail: ivanildaramosmelo@gmail.com

Aluminum is one of the most versatile materials used in engineering, architecture and other industry segments. The expanded use of aluminum and its alloys in industries is due to its high corrosion resistance in some harsh environments such as seawater, however, some welding processes may favor localized corrosion. The objective of this study was to evaluate biofilms formation and biocorrosion process in AA7075 aluminum FSW welded joints in systems containing anaerobic bacteria (SRB), aerobic bacteria (E. coli) and sterile seawater. Static system glass reactors were used for a period of 15 days, being monitored through the quantification of BRS and E. coli (planktonic and sessile), Scanning Electron Microscopy (SEM), Spectroscopy X - Ray (EDX), corrosion rate and gel visualization test. The results showed that there was variation in microbial adherence at the end of 15 days. Corrosion rates were classified as low in the studied systems. The highest corrosion rate value was in the system containing sterile seawater. Specimens submitted to systems containing aerobic and anaerobic bacteria were not affected by the corrosion process within the first 15 days of exposure.

Study of the Hall-Petch relationship for a medium-entropy alloy with carbon addition after severe plastic deformation

Guilherme Cardeal Stumpf[1,2,3], Francisco Gil Coury[4], Roberto Braga Figueiredo[5], Witor Wolf[5]

e-mail: guicstumpf@gmail.com

Among the toughest engineering materials known by men are the Cr-Co-Ni face-centered cubic (FCC) alloys. These multi-principal element alloys (MPEAs) have low stacking fault energy (SFE) and can deform plastically by twinning and phase transformation in addition to slip. Studies show that small additions of carbon can increase the strength of CrCoNi with minimal ductility loss. Likewise, grain refinement is also a strengthening mechanism that is notable for good trade-off between both properties. In an effort to combine these phenomena and obtain even higher mechanical properties, we processed a $Cr_{39.6}Co_{30}Ni_{30}C_{0.4}$alloy via high-pressure torsion (HPT). A base alloy without carbon addition, $Cr_{40}Co_{30}Ni_{30}$, was studied concurrently for comparison. Both materials were manufactured through arc-melting of the high purity individual elements. The alloys were thermo-mechanically processed multiple times with cold rolling followed by annealing. Then, the fully recrystallized samples were severely deformed by 5 rotations of HPT with 6 GPa at 1 rpm. A low-temperature heat treatment was employed to induce relaxation of the deformed substructure. Afterwards, the samples were annealed for full recrystallization and minimal grain growth. For all conditions the hardness values were measured with a Vickers microindenter throughout the disk’s diameter. Grain s were measured with electron backscatter diffraction in a scanning electron microscope and in a transmission electron microscopy with the automatic crystal orientation/phase mapping technique. A Hall-Petch (HP) curve was plotted and compared to that of the samples annealed after cold rolling (grain s measured with optical microscopy). The ultra fined-grained alloys resulted in a deviation of the HP relationship

Study of the mechanical properties of the commercial alloys A356 used in the automotive wheels

Adriano Tonetti[1], Sâmia Morato Faria[2], Eder Lopes Ortiz[1], Wisley Riuper Ramos osorio[1], Ausdinir Danilo Bortolozo[3], Giovana da Silva Padilha[4]

[1]Universidade Estadual de Campinas (*Faculdade de Tecnologia*) , [2]Universidade Estadual de Campinas (*faculdade de Ciências aplicadas*) , [3]Universidade Estadual de Campinas (*Faculdade de Ciências aplicadas*) , [4]Universidade Estadual de Campinas (*Faculdade de ciências aplicadas*)

e-mail: adriano.tonetti@hotmail.com

Al-Si-Mg system (e.g. A356 alloy) is widely used in manufacturing components for the automotive such as the wheels. When heat treatment (T6) is performed in this alloys, microstructural changes that include homogenization, better distribution of alloying elements and dissolution of soluble phases with Si and Mg and spheroidization of eutectic particles resulting in a notable improvement in mechanical properties.

Based on this premise, this study proposes to explore the microstructure-mechanical properties correlation of the A356 alloy subjected to T6. Different quench rates and artificially aging were used. Initially, the samples were solubilized at 540°C for 5 h. Then, they were immediately immersed in water (quenching) at 30°C, 60°C and 80°C for 2 min. The third step after water quenching, precipitation hardening at 180±3 °C, 200±3 °C and220±3 °C during 5 h is carried out.

The results without T6 showed a phase rich in silicon in lamellae shape, where as in the treated samples, this phase rich in silicon migrated to rodshape. The mechanical tests showed an increase almost 30% in UTS (UTS before T6:167.1±6 MPa; UTS after T6 using quenching of 30 °C: 239.1±7 MPa). The hardness measurements results followed these changes with an increase close to 25% (hardness before T6: 69±3 HV; hardness after T6: 92±4 HV).

SEM analysis showed that coarse silicon particles are modified to smaller spheroidized particles. Upon solubilization, the acicular silicon platelets in the unmodified structure begin to decompose into smaller fragments and gradually spheroidize.

The results indicate that T6 changes the shape of silicon, from lamellar to rods, through a process of fragmentation and spheroidization,providing an increase in hardness and UTS. However, the artificial aging decreases the mechanical properties. This fact suggests that over aging has probably been reached.

Study of the potential application of lemon essential oilas a corrosion inhibitor of the carbon steel in acid médium

e-mail: mauriciosvas@hotmail.com

Steels are ferrous alloys widely used in various industrial applications: civil construction, transportation, oil and gas, marine, petrochemicals, automotive. Alloy classified as ASTM A36 is a kind of carbon steel, which has interesting mechanical properties but does not have good corrosion resistance. The high corrosion susceptibility of this steel occurs because, unlike stainless steels, these alloys do not form passive films [1-3]. In view of the costs generated by corrosion and the different applications of carbon steel, several anticorrosive methods have been researched. Recently, a new class of corrosion inhibitors has been studied, the so-called green inhibitors corrosion. These materials have a combination of corrosion inhibiting properties with low toxicity. Recent research has observed that essential oils can be an interesting alternative to classic corrosion inhibitors [1-3]. Considering the extensive use of carbon steel, the costs of corrosion and the need to obtain anticorrosive techniques that have an environmentally friendly behavior, this work evaluated the use of lemon essential oil as a corrosion inhibitor of ASTM A36 steel in acid medium. Immersion tests were used to determine the steel corrosion rate and essential oil inhibition efficiency in 0.1M HCl. The tests were conducted in a naturally aerated medium and at a temperature of 25oC. The results showed that lemon essential oil acted as a steel corrosion inhibitor for the two evaluated concentrations (1000 and 3000 ppm). It was observed that the inhibition efficiency was more significant for the highest evaluated concentration of essential oil.

Study of the tribological efficiency of DLC thin film coatings on thermoplastic injection mold extractionpins

DIEGO CHIARELLO[1], Alexandre Luís Gasparin[1]

[1]Intituto Federal do Rio Grande do Sul

e-mail: diego.chiarello@caxias.ifrs.edu.br

Diamond-like carbon (DLC) thin films are amorphous hydrogenated carbon (a-C:H) materials that constitute a surface coating technology, with potential for improving the mechanical and tribological properties of materials [1]. In this study, extraction pins for thermoplastic injection molds, produced in AISI H13 steel, were coated with DLC films using the PECVD (plasma-enhanced chemical vapor deposition) technique, using a silicon interlayer to increase the film adhesion to the substrate [2]. The DLC-coated pins were subjected to a cyclic wear test on a bench device, which simulates the working conditions of the extraction pin when mounted in the injection mold. In the wear test, different lubrication conditions were tested, in order to compare properties and verify the efficiency of the coating.Comparative measurements of sample mass loss after the test, demonstrated that lower wear occurred in samples where the use of lubricating grease was not applied, confirming in practice one of the main properties attributed to DLC films, acting as a solid lubricant due to its low coefficient of friction, thus eliminating the need for lubricating grease [3]. On the other hand, the samples tested with lubricating grease showed a higher wear rate due to the formation of an abrasive paste between the DLC film and the grease during the test. Additionally, scanning electron microscopy (SEM) analysis performed on the surface of the tested pins demonstrated that the film did not exhibit any failures during the test, maintaining adhesion to the substrate, and only wear marks were observable from the test. Moreover, a scratch test analysis was performed on the pin surface, which resulted in high film adhesion values to the substrate and a low coefficient of friction in the range of 0.02. The results obtained demonstrate the efficiency of the coating and prove the possibility of applying DLC to replace the use of lubricating grease in the analyzed components

Surface morphology characterization of oxidized NiTiNb shape memory alloy

CLAUDIO BESERRA MARTINS JÚNIOR[1], Rodrigo Silva[2], Piter Gargarella[3,4], Carlos Alberto Della Rovere[5]

[1]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais*) , [2]Federal University of Sao Carlos (*Department of Materials Engineering*) , [3]Univerdade Federal de São Carlos (*Department of Materials Engineering*) , [4]Federal University of Sao Carlos (*Materials Engineering*) , [5]Univerdade Federal de São Carlos (*DEMa*)

e-mail: claudio_junior_jua@hotmail.com

Since the Shape Memory Effect (SME) discovery, scientific interest in this unique property has grown exponentially. NiTi-based are the most commercially important shape memory alloys (SMA) today, due to properties such as high shape recovery and the possibility of becoming biocompatible. Despite the countless researches studying the physical metallurgy of this alloy system, obtaining them inexpensively is still a challenge for industries. One of the costly factors is the need to use an inert atmosphere to prevent oxidation, so it is critically important to study methods to improve the oxidation resistance of NiTi SMAs. One investigation line is the addition of ternary element, where Nb stands out. There are several strategies used to investigate high temperature oxidation behavior, one of them being the characterization of the oxide surface morphology. In this type of analysis, the continuity of the oxide outer layer is verified, as are the shape and dimensions of the grains present. On this basis, the aim of the present work was to verify the influence of 10.5 at.% Nb addition on the surface morphology of NiTi SMAs oxidized at 800 °C for up to 100 h, and at 900 °Cand 1000 °C for 4 h. The results showed that in all cases, except for the binary alloy at 1000 °C (which formed a very porous oxide), the crystals formed are in a faceted shape and the layer is continuous along the alloy surface. With increasing exposure time (from 4 to 100 h at 800 °C) or increasing temperature from 800 °C to 900 °C, it can be seen that the crystalsbecome increasingly thicker, but keep the same geometrical aspect, which suggests maintenance of the oxidation mechanism. At 1000 °C, for both alloys a change ofmechanism seems to have occurred. The ternary alloy exhibits considerably smaller oxidegrains compared to the binary alloy, which indicates high effectiveness of Nb in improvingoxidation resistance.

Surface Plasmon Resonance Spectrometer in the Double Prism Configuration: Fast Characterization of the Dielectric Constant Dispersion of Thin Films

Debora Cristina da Silva[1], Marcelo Gonçalves Vivas[2] [1]Universidade Federal de Alfenas (*Ict*) , [2]Universidade Federal de Alfenas (*ICT*)

e-mail: debora.silva@sou.unifal-mg.edu.br

Surface plasmons are electron collective oscillations in a metal/dielectric interface. Plasmons exhibit very interesting characteristics such as wavelength smaller than the visible photons, propagation length on the micrometer scale and penetration depth into dielectric and metal on the order of nanometers. These remarkable features have been widely applied in reduced-scale devices and biosensing. SPR devices generally are based on the Kretschmann configuration, in which a laser beam is used to excite plasmons in a metal-coated prism surface. However, this configuration is painful (monochromatic) and does not allow for obtaining the dielectric constant and thickness simultaneously. To overcome this problem, we have developed a SPR spectrometer completely automated through the double prism Kretschmann’s configuration. Our SPR spectrometer consists of a halogen lamp witha tungsten filament (300-2000 nm), a motorized rotation stage (minimal step of 0.0003 degrees) containing the double prism configuration and an optical fiber coupled to a portable spectrometer. The double prism configuration simplifies the experimental setup, avoiding adding another rotation stage to the optical system. To calibrate the SPR spectrometer, we initially measured the refractive index dispersion relation (400-1000 nm) of the BK7 prism. After that, putting a nanometric gold thin film (33 nm) on one of the prism's faces, we obtained the SPR curves as a function of the wavelength and incident angle. Through the theoretical model based on Fresnel equations and the iterative Least Squares Method (LSM) it was possible to determine the dispersion (400-1000 nm) of the real (Re{E})} and imaginary (Im{Ɛ}) part of the dielectric constant of the gold film.

Synthesis and Characterization of a new Cu(I)-Iodide polynuclear complex with N-Donor ligand for luminescence and thermochromism studies

Carlos Cordeiro Schneider[1], Tiago Pacheco de Camargo[1], Renata Danielle Adati[1]

[1]Universidade Tecnológica Federal do Paraná (*DAQBi*)

e-mail: carlosschneider95@gmail.com

In materials chemistry, molecular design is interesting for creating optical devices such as OLEDs or WLEDs and luminescent paints. The coordination chemistry of Cu^I has been extensively studied due to its abundance in results with organic and inorganic ligands, with variations in its structure, ranging from a simple mononuclear complex to extensive coordination networks Complexes based on Cu^I-Iodide nanoclusters (NCs) have drawn attention due to their luminescent properties in the visible region, in addition to their simple synthesis with different ligands, control of their physicochemical properties and excellent optical properties. These NCs have polynuclear Cu^I-Iodide structures coordinated with organic ligands that increase luminescent efficiency, such as rigid aromatic N-donor ligands, showing different conformations and units, the most common of which is the cubane tetramer Cu_4I_4 [1]. The aim of this work is the synthesis and characterization of onecubane tetramer unit complex, already known in the literature [2], $[Cu_4I_4Py_4]$ (Py = pyridine), and a new complex, $[Cu_4I_4TMX_4]$ (TMX = 1,3,7-trimethylxanthine) for analysis of their luminescent and thermochromic properties. The complexes were synthesized and characterized by multiple techniques, displaying a characteristic luminescence when exposed to a 254 nm UV light. As the final goal, the complexes will be used to build up luminescent films in order to study their applicability in optical materials.

e-mail: afbugarin@usp.br

This work aims to investigate the corrosion performance of the UNS S32101 lean duplex stainless steel (LDSS) welded by the gas tungsten arc welding double fusion (GTAW-DF). In the study, six welded samples were manufactured with different welding parameters. A Syringe cell was used to characterize the electrochemical behavior of the different welded zones by potentiodynamic polarization tests in NaCl 3,5 % (w.t.) and in a solution of citric acid with addiction of NaCl to simulate the food industry. The results showed that the welding parameters tested significantly affected the corrosion resistance of the LDSS UNS S32101. Besides, a correlation was stablished between microstructure and electrochemical behavior of fusion line (FL), heat affected zone (HAZ) and fusion zone (FZ).

The effect of C and N on the mechanical behavior of medium-Mn steel

e-mail: lucas.otani@ufscar.br

High and medium-Mn steel belongs to the class of Advanced High-Strength Steels (AHSS). The outstanding mechanical properties come from the fully austenitic microstructure which might present induced plasticity mechanisms (TRIP or TWIP) [1]. The stacking fault energy (SFE) is one of the main parameters to describe the deformation mechanism, however, the effect of interstitials is not well assessed in the literature. Only a few studies involving N additions are presented in the literature for this class of alloys and the objective of this study is to observe the effect of the main interstitials (C and N) on the mechanical behavior of medium-Mn steels [2]. Four compositions were designed by thermodynamic models and defined considering the following plan: without interstitials, with C additions, with N additions, and the last with both C and N additions. The samples were produced by arc melting, hot rolling followed by cold rolling and annealing treatment to obtain a homogeneous microstructure. Tensile tests were performed, and it was observed that the alloy in which the austenite was more stable compared to the martensite (with both C and N additions) presented the highest ductility among the studied compositions, and the alloy with only C presented higher ultimate tensile stress.

The effect of Co additions in titanium aluminides processed by powder metallurgy

Lorenzo Quaglio[1], Warlen Alves Monfardini[1], Juliano Soyama[1]

[1]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*)

e-mail: l201645@dac.unicamp.br

Titanium aluminides are intermetallic materials with low density and high mechanical properties at high temperatures [1]. Typical processing routes include casting and thermomechanical treatments and are extremely costly. Therefore, less expensive processing techniques such as powder metallurgy become interesting alternatives for these class of materials. One of the greatest challenges of powder metallurgy processing of titanium aluminides corresponds to their high sintering temperatures (>1400 °C) [2]. In this work, processing of Ti-45Al with Co variations between 1-10 at.% was conducted with the aim of lowering the sintering temperatures since Co can induce liquid phase during sintering [3]. The results indicate that there was a systematic decrease in porosity with Co additions and a significant decrease in the sintering temperature. The microstructure changed from fully lamellar with 1 at.% Co to duplex with higher Co additions and an increase in hardness was also observed.

Nb-added aluminum alloys present in their phase equilibrium diagram thermodynamic uncertainties in the phase transformations during the solidification path [1-3]. In this sense, the main objective of this work was to elaborate an experimental and theoretical study with Al-3Cu-xNb (x=0.5, 3 and 5w.%) alloys in order to obtain the simulated (or theoretical) solidification paths by the respective phase equilibrium diagrams of the investigated alloys, as well as through experimental cooling curves. The thermodynamic Thermo-Calc tool was used to obtain the phase diagrams of these alloys, and a solidification apparatus was developed and used to obtain experimental cooling curves with cooling rates for thermodynamic no-equilibrium conditions, as well as cooling and heating curves using the differential scanning calorimetry (DSC) technique were obtained with cooling rates close to equilibrium conditions. For all studied Nb compositions, the simulations showed the following peritectic reaction (PR): Liq. $\rightarrow Al_3Nb + Al\alpha$, confirmed by experimental equilibrium solidification curves (DSC). On the other hand, microstructure analyzes for non-equilibrium cooling conditions only confirmed the PR for Al-3Cu-xNb alloys (x=3 and 5wt.%).

The use of titanium alloys as a biomaterial has been commonly applied because they have good mechanical properties, excellent biocompatibility, and excellent corrosion resistance. Despite being a promising material in the biomedical area, health problems due to premature failures, among other complications that alter the functioning of these devices, occur frequently. In this research the technique used aims to work the surface of the alloy increasing the thickness of its natural oxide layer, improving its properties, enabling structural, compositional and morphological changes in the coating of the oxides. The study alloy, Ti35Nb5Ta, submitted to the anodizing process, under controlled thermal behavior, had its samples forged by plastic deformation, through chemical pickling, cutting and weighing, submitted to the arc melting procedure to obtain the alloys. The chemical, structural, microstructural and mechanical characterizations were performed by energy dispersion spectrometry (EDS), X-ray diffraction (XRD), optical microscopy (OM) and scanning electronics (SEM), Vickers microhardness and Young's modulus. It is expected through the analysis of optical microscopy to visualize the of the grain contour as well as its distribution, the presence of elements such as Al,Si,S,Fe in the composition of the alloy by x-ray fluorescence, determination of the β phase via XRD, and how this phase acts on Young's modulus, and the values of microhardness and elasticity, whether they are larger or smaller in comparison to commercially used alloys, and whether there is presence of other structures that may influence the strength of the alloy.

Tribological properties of a β titanium alloy processedby angle pressing in equal channels (ECAP)

Rodrigo Morato de Souza Perfi[1], Alexandre Neves Ribeiro[1], Sydney Ferreira Santos[2]

[1]Federal University of ABC, [2]Federal University of ABC (*CECS*)

e-mail: rodrigo.perfi@aluno.ufabc.edu.br

Titanium and its alloys are widely used in several industrial sectors, including aerospace, biomaterials, energy, and so on. To address the technological requirements of these applications, new titanium alloys have been continuously developed, mainly β-titanium alloys which are attractive for biomedical and energy-related applications. In this work, the effect of the severe plastic deformation process (SPD) of equal channel angular pressing (ECAP) on the tribological properties of the Ti-29Nb-13Ta-4Mo β-Ti alloy is investigated. In ECAP, a metallic specimen is pressed though a metallic die containing two channels, equal in cross section area, intersecting at a die angle, where it is constrained and bent through a sharp angle which imposes high plastic shear strain in material without any reduction in cross-section area. In this work, ECAP processing was performed using a die with 120º between the channels. ECAP was performed up to 8 passes at 350oC by route A (no specimen rotation between the ECAP passes). The tribological properties of as-received and ECAP processed samples was performed using a reciprocating nanotribometer Anton Paar - NTR³. The interplay between the alloys' microstructures, ECAP processing, and tribological properties are discussed in this work.

Multi-principal element alloys (MPEAs) are a new class of materials that are characterized by the absence of a primary element in their composition [1]. The Cr33Co33Ni33 (at.%) alloy, derived from the Cantor alloy (Cr20Co20Ni20Mn20Fe20 (at.%)), stands out in the literature due to its excellent mechanical properties at room and cryogenic temperatures [1]. However, there are contributions to the mechanical properties of the Cr33Co33Ni33 alloy that have not been fully elucidated. One of the possible contributions is Short-range ordering (SRO). This phenomenon can be defined as the coordination preference of a certain constituent element in the alloy by another, affecting up to 2 atoms relative to the central atom [2]. Due to the small scale of SRO formation, which is in the nanometer range, this phenomenon presents difficulties in detection, generating ambiguities in the literature. Therefore, the present work aims to assess the formation of SRO in 2 compositions Cr33Co(33-x)Ni(33+x) (x=0, 33) through isothermal treatments at low temperatures (475 °C) for different times. The goal is to verify, through indirect detection techniques (thermal capacity analysis, microhardness, and synchrotron DRX), whether the SRO phenomenon occurs, complementing the literature with more information about the SRO for the CrCoNi system.

e-mail: evaldohoffmannfaculdade@gmail.com

Among the various aluminum alloys registered today, we can highlight those that use copper, usually added in levels between 1 and 5%, promoting an increase in hardness and mechanical strength of aluminum alloys, in addition to allowing them to be heat treatable [1]. Niobium is a soft, ductile metallic element, with a specific mass of 8.57g/cm³ and a melting point of 2,468°C. It also has good resistance to corrosion due to the formation of a superficial oxide film responsible for its passivation [2]. Considering the aforementioned importance of Al-Cu alloys, and observing the continuous development of research related to niobium and its importance for Brazil, this work has as main goal to evaluate the effects of thermal solidification parameters, such as growth and cooling (V_L, T_R) on primary dendritic spacings (λ_1) in an Al-3Cu-5Nb (wt.%) alloy, using rates a water-cooled horizontal solidification device. Optical microscopy techniques were used to characterize and quantify the length of the microstructural scale. The $\lambda_1$variation with $V_L$and $T_R$was established by means of mathematical expressions given by the formulas $\lambda_1 = 60(V)_L^{-1.1}$, $\lambda_1 = 214.7(T_R)^{-0.55}$, with the exponent values -1.1 and -0.55 agreeing with those proposed by works carried out in the literature for aluminum-based alloys.

e-mail: mariaestillac@gmail.com

Monotectic alloys, especially Al-Pb alloys, have interesting mechanical and thermophysical properties for various industrial applications, such as the manufacture of antifriction materials and electronic components [1]. However, due to the toxicity of lead, more sustainable alternatives are being sought for these applications [2]. The study of aluminum-lead alloys is crucial for identifying their unique properties and developing suitable alternatives. This knowledge can lead to safer, more efficient, and more environmentally friendly products. Thus, to expand studies on Al-Pb alloys and to evaluate the influence of more intense convective flow in the solidification of hypermonotectic alloys, this work aims to study the solidification kinetics of an Al-2.3wt%Pb alloy solidified in a downward vertical device. The gap between the solidified metal and the mold resulted in lower values for both growth and cooling rates compared to similar results in an upward solidification [3], although the directionality of heat extraction was maintained, as observed in the macrostructure.

Use of digital image correlation technique in tensile testing of functionally graded materials produced by additive manufacturing.

Matheus Valentim[1], Gilberto Vicente Prandi[2], Rubens Caram[2]

[1]Universidade Estadual de Campinas (*Departamento de Engenharia de Materiais e de Manufatura*) , [2]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*)

e-mail: m242838@dac.unicamp.br

Selective laser melting (SLM) is an effective method for producing functionally graded materials. In the SLM technique, metallic powder layers are sequentially deposited onto a substrate and selectively melted using a laser beam to achieve precise control over the geometry and composition of each fabricated layer. It enables the production of multi-material structures with tailorable properties by integrating the structures and functions of various materials [1]. In this new class of materials, the mechanical response, under tensile load, is highly heterogeneous. Therefore, a precise tool is required to obtain quantitative measurements of the locally specific strains. Digital Image Correlation (DIC) has emerged as a viable alternative. DIC is a computational and optical measuring method capable of obtaining deformation and strain fields in multiple scales and has been increasingly used to study stress-strain behavior. This technique requires a set of images recorded during tensile tests and computationally tracing the pixels to aim the displacements through images by the grey intensity of the grid matrix [2]. The aim of this research is to develop a DIC algorithm witha graphical user interface that facilitates its use. To achieve this, open-source technologies and well-known programming languages will be employed. This work also includes the validation of the developed system by comparing it with conventional systems. The developed algorithm was used to perform and analyze tensile tests on various materials. Virtual extensometers were employed to monitor the elastic and plastic deformations of the specimens. The results demonstrate that the digital image correlation technique is a highly effective tool for analyzing functionally graded materials.

Wear-resistant Fe-Cr-Mo-Nb-B coating by plasma transferred arc

Luana Cristina Miguel Rodrigues[1], Guilherme Yuuki Koga[2], Ana Sofia Clímaco Monteiro D' Oliveira[3], Claudemiro Bolfarini[2], Claudio S. Kiminami[2], Walter Botta[4]

[1]Univerdade Federal de São Carlos (*Engenharia de Materiais - PPGCEM*) , [2]Univerdade Federal de São Carlos, [3]Universidade Federal do Paraná, [4]Univerdade Federal de São Carlos (*Engenharia de Materiais*)

e-mail: luanacmiguel@gmail.com

Fe68Cr8Mo4Nb4B16 gas-atomized powders were employed to coat carbon steel substrates through the Plasma Transferred Arc (PTA) process. Four processing conditions were considered: A, B, C e D. For condition A and condition B the powder feed rate was 10 g/min and current were 120 A, varying only the particle size range: 106 - 180 μm and 53 - 106 μm, respectively. For condition C and condition D, the powder feed rate was 6 g/min, using powders with a granulometric range of 53 - 180 μm, being 50% powders with a particle sizeof 53 - 106 μm and 50% powders with particle size 106 - 180 μm, changing only the current: 120 A and 180 A respectively. The coatings were evaluated by X-ray diffraction (XRD), scanning electron microscopy (SEM), optical microscopy (OM), differential scanning calorimetry (DSC), transmission electron microscopy (TEM) and confocal microscopy (CM). The Vickers microhardness was analyzed in the top and cross section of the polished coatings. Tribological tests were performed based on the standard (ASTM G133-05) onpolished surfaces (Al2O3 1-μm), in pin-on-plate reciprocal configuration. Preliminary resultsindicated: i) coatings with refined microstructures, composed of M2B - tetragonal hard boride ii) Fe dilution of the coating on the substrate ~ 23%; iii) Vickers Microhardness ~370 HV0.5; iv) and abrasive wear resistance ~ 1.7 x 10-4 mm3N-1m-1. Such results demonstrate that the Fe68Cr8Mo4Nb4B16 alloy is viable to be used in steel coating processes by PTA. Wetting, IMC types and IMC layer growth of a Sn-Bi-In alloy in Cu, Ni and Fe-36Ni pads during reflow soldering

Jaderson Rodrigo da Silva Leal[1], Rodrigo André Valenzuela Reyes[2], Guilherme Lisboa de Gouveia[3], Francisco Gil Coury[4], José Spinelli[5]

[1]Federal University of Sao Carlos (*PPGCEM - DEMa*) , [2]Univerdade Federal de São Carlos, [3]Federal University of Sao Carlos, [4]Univerdade Federal de São Carlos (*Engenharia de Materiais*) , [5]Federal University of Sao Carlos (*DEMa*)

e-mail: jaderson.leal@estudante.ufscar.br

Currently, the development of new lead-free alloys with low melting point for use in soldering reflow operations of electronic components is increasingly widespread. Recent studies [1-3] demonstrated that Sn-based alloys containing In showed significant reductions of either the contact angle or the interfacial growth of the intermetallic compound (IMC). In the present work the effects of 10 wt.% In addition on the wettability and reaction layer growth/nature of the Sn-40wt.%Bi alloy in copper, nickel and Invar (Fe-36Ni) pads were examined. The solder reflow was carried in inert Argon atmosphere, for samples aged to 180 °C at a rate of 10 °C/min and maintained at that temperature for 15 min, followed by cooling to room temperature at approximately the same rate. The samples were aged at a temperature of 120 °C for 120 h. The layers were characterized by optical microscopy (OM), scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS), and wetting angle measurements. The ternary alloy had a reduction from 49.2±0.2° to 23.6±1.6° in contact angle compared to the binary Sn40wt.%Bi on Cu substrate. In the Ni and Invarsubstrates, the angles were 46.5±2.9° and 40.4±0.9° respectively. Punctual EDS analysis ofthe ternary alloy on Cu substrate revealed the growth of the Cu6(Sn,In)5 IMC, with substitutive incorporation of In in place of Sn in the crystal lattice (7.53at.%). The Ni3Sn4 IMC formed in the Ni/alloy couple showed more regular morphology, with very low interaction with In (0.98 at.%). The percentage growth of the layer thickness up to 120 hwas 6.7%. Finally, on the Invar substrate, the IMC showed thin and uniform features,containing high In content (65.10 at.%).

O-Recent Advances in Cold Plasmas and Related Applications

Active diagnostics of electrolytic plasma processes for surface engineering of advanced materials

Aleksey Yerokhin[1], Aleksey Rogov[1], Allan Matthews[1]

[1]University of Manchester (*Materials*)

e-mail: Aleksey.Yerokhin@manchester.ac.uk

Electrolytic plasmas are of increasing interest for many applications, including surface engineering of advanced materials. Important plasma properties that determine processing efficiency depend on charge transfer pathways at the electrode-electrolyte interface that occur under complex polarisation conditions. To understand these pathways, we developed original methods of real-time electrical diagnostics, such as in-situ impedance spectroscopy, pulse transient analysis and dynamic voltammetry, and applied them to a group of electrolytic plasma processes, including Plasma Electrolytic Oxidation (PEO). New data obtained reveals kinetically driven effects associated with both solvent electrolysis and chemical rearrangements in the surface layer, which allows transition from microarc to soft sparking regime during PEO processing of valve metals to be explained. Emerging evidence indicates that dynamic anodic behaviour of these metals during pulse-reverse polarisation is influenced by both prior cathodic biasing and spontaneous processes taking place under unpolarised conditions. This implies the existence of quasi-equilibrium states with characteristic time constants of the order of tens to hundreds of milliseconds that can be attributed to quasi-reversible hydrogen intercalation into the anodic oxide. The insights achieved allow practical recommendations to be made for the rational design of intelligent electrolytic plasma processes providing controllable growth of PEO coatings on complex shape components and enabling PEO processing of metal substrates with large surface area.

A low-cost atmospheric pressure plasma jet for applications in oral medicine

Konstantin Georgiev Kostov[1], Fellype do Nascimento[2], Torsten Gerling[3], Aline da Graça Sampaio[4], Mariana Raquel da Cruz Vegian[5], Diego Morais da Silva[4], Cristiane Yumi Koga Ito[4]

e-mail: konstantin.kostov@unesp.br

In the last decade, non-thermal atmospheric pressure plasma jets (APPJs) have been extensively investigated as an alternative therapeutic option for diverse biomedical procedures. Nowadays, plasma medicine encompasses a wide scope of applications ranging from microbial inactivation to cancer treatment and wound healing [1]. The necessity of treating areas of difficult access, such as inside human body cavities, motivated the development of APPJ generated at the extremity of a long flexible plastic tube [2]. In this way, the reactive species produced by the plasma can be safely delivered to a chosen spot, leading to a novel plasma jet application field called plasma endoscopy [3]. This work reports on the study of a low-cost plasma jet device developed at FEG-UNESP that is mostly aimed at applications in dentistry.

Dry Coatings by Cold Plasma for the Innovation in Regenerative and Reparative Medicine

Diego Mantovani[1], Pascale Chevallier[2], Andranik Sarkissian[3]

[1]Université Laval (*Min-Met-Mater Eng, Lab Biomaterials and Bioengineering*) , [2]Université Laval (*CR-CHU de Québec*) , [3]Plasmionique

e-mail: diego.mantovani@gmn.ulaval.ca

Over the last 50 years, biomaterials, prostheses and implants saved and prolonged the life of millions of humans around the globe. Today, nano-biotechnology, nanomaterials and surface modifications provide a new insight to the current problem of biomaterial complications, and even allows us to envisage strategies for the organ shortage. In this talk, creative strategies for modifying and engineering the surface and the interface of biomaterials, including metals, polymers from natural and synthetic sources, will be discussed. The unique potential of low-pressure low-temperature plasma surface modification will be detailed with the overall aim to envisage today how far innovation can bring tomorrowsolutions for reparative and regenerative medicine. Applications for health will be emphasized, including biologically active-based, biomimetic, low-fouling, bactericidal, and antiviral coatings.

e-mail: vinodinivijay@yahoo.fr

This work reports on the demonstration of the penetration of cosmetic active ingredients (caffeine and hyaluronic acid) in human skin explants following safe and controlled plasma jet exposure. First, temperature, current and biological markers fluorescence associated with various proteins in the stratum corneum and epidermis were measured to check the safe delivery of plasma jet and to select two operation regimes at 1 and 20 kHz. Plasma exposure for tens of seconds is shown to induce a transient modulation of pH, transepidermal water loss and water contact angle revealing a reversible skin barrier function disturbance. Then it is demonstrated that plasma exposure first significantly accelerates the penetration of active ingredients, detected about 30 mn after their topical application following plasma exposure instead of about 6 hours in the control samples not exposed to plasma. Second the tuning of the plasma jet pulse repetition rate allows to control the penetration kinetics. Such ex vivo results agree with previous in vitro experiments [1] also exhibiting a transient permeabilization time window. To the best of our knowledge, this work is one the very first demonstration, beyond preliminary investigation by [2], of safe and controlled plasma-assisted active ingredients skin penetration in the context of cosmetic applications.

Metallic nanoparticles plasma synthesis from organometallic precursors

Laurent Houssiau[1]

[1]Université de Namur (*Physics*)

e-mail: laurent.houssiau@unamur.be

Our group has developed a novel, environment-friendly method for synthesizing metallic nanoparticles (NPs) from solid organometallic precursors decomposed by plasma. In this talk, we will review various applications of this method, with a focus on catalysis in fuel cells. Our approach involves mixing organometallic powders with nanostructured carbon and decomposing them in a low-pressure RF plasma discharge, resulting in a fine dispersion of metallic NPs on the carbon substrate. We use TEM, XRD, and XPS to characterize the morphology, crystallinity, and chemistry of the produced materials, respectively, and assess plasma chemistry with OES.

We will first discuss the synthesis of Pt NPs from three different precursors, which are widely used in proton exchange membrane fuel cells. Next, we will present the synthesis of Ni NPs in inert, reducing, and oxidizing plasma conditions. In the third part, we will describe our work on producing bimetallic Ni-Pt NPs [1] to decrease the amount of Pt needed for catalysis, using a single-step or a two-step plasma process. Small, finely dispersed bimetallic NPs were obtained in the two-step process, combining low and high energy treatments. Finally, we will briefly showcase other NP syntheses, including ZnO for photocatalysis, ferromagnetic Fe_xN, PtCu alloys, and Au NPs on TiO_2.

Overall, organometallic plasma decomposition is a versatile way to produce a variety of metallic NPs, including alloys, thanks to the multiple plasma parameters that can be adjusted, such as chemistry, power, time, pulse rate, and single or multiple steps. This one-pot process is fast, solvent-free, and consumes little energy, making it a promising method for NP synthesis.

OPPORTUNITIES OFFERED BY SUSTAINABLE DEVELOPMENT GOALSIN PLASMA SURFACE TREATMENTS OF METALLIC SURFACES

czerwiec[1,2]

[1]Institut Jean Lamour, [2]Université de Lorraine

e-mail: thierry.czerwiec@univ-lorraine.fr

The Sustainable Development Goals (SDGs), also known as the Global Goals, were adopted by the United Nations (UN) in 2015 to ensure that by 2030 all people enjoy peace and prosperity. Materials-related issues can be found in many of the 17 sustainable development goals. In this context, surface engineering not only makes it possible to confer new properties on materials, but also to reduce volumes and masses of materials for a given application. Most of the surface treatments currently carried out in metal-related industries are realized in the liquid phase. The context of the Registration, Evaluation and Authorization of Chemical Substances (REACH) legislation leads many manufacturers to take an interest in gas phase surface treatment like plasma surface treatment or in less hazardous liquid phase like plasma electrolytic oxidation compared to anodizing.

In this presentation, we will give some examples of surface treatment by plasma applied to different SDGs. Surface treatments are found in a number of SDG. It is in SDG 7: affordable and clean energy that great opportunities arise and will arise for plasma assisted surface treatment of metals. We will discuss surface treatments in power plants for energy production (nuclear, solar), surface treatment for corrosion and wear sensitive materials, surface treatments for the hydrogen economy. Surface treatments for thermal management will also be developed in this presentation.

The case of SDG 12: responsible consumption and production is particularly important for surface treatments that must integrate the life cycle assessment. A relevant issue for surface treated products is the end-of-life or demanufacturing. In most cases, the recycling of surface treated products is difficult and the cost for recycling is high. The surface treatments of the future will have to integrate recycling aspects

Use of Pulsed Plasma in Science and Industry

Marcello Filgueira[1]

[1] *Universidade Estadual do Norte Fluminense Darcy Ribeiro (LAMAV)*

e-mail: marcello@uenf.br

Pulsed plasma used to process advanced materials is not a novelty for the science, since it has been studied for some 4 decades. A lot of advantages have been experienced by materials when pulsed plasma processed, such as mechanical and physical properties' improvements. In this scenario, some discussion raises up in this interesting topic upon the pulsed plasma processing of materials focused on Pulsed plasma Sintering - SPS, by considering the evolution of this manufacturing technique, scientific approaches, discussion upon the existence of micro-plasma, case studies, and the use of SPS to manufacture parts in industry, considering the adoption of the 4.0 Industry premises.

e-mail: luis.fontana@udesc.br

In this paper we discuss different methods used for the generation of non-thermal, low-temperature plasmas with special emphasis on plasmas sources developed at LabPlasma/UDESC/Brazil. We also discuss technical achievement of plasma sources for different technological applications. Among the plasmas described include a new Asymmetric Bipolar Plasma Power Supply (ABiPPS), adjustable in frequency, amplitude, and pulse width for the generation of plasmas with high energy electrons. The increase in the electrons average energy is achieved by intense positive pulses of short duration (in order of nanoseconds) that increase the electrodes secondary electrons emission, allowing controlled plasma ionization amplification. The positive pulse intensity adjustment also allows the control of the ionized mass volume, besides plasma generation with low negative polarization values. The ABiPPS system allow us to controll some plasma parameters in a independent way, which make this system suitable for several applications, namely, plasma sputtering, surface treatment, nanoparticles functionalization, plasma polymerization, etching, surface functionalization of polymers and ceramics, besides other. Others plasma sources developed at Labplasma will be presented, namely, Thin Mesh Cathodic Cage Plasma and DBD plasma for nanoparticles functionalization.

Development of a plasma-based platform for Ag-controlled release profile for antibacterial applications

Linda Bonilla[1], Pascale Chevallier[2], Andranik Sarkissian[3], Diego Mantovani[4]

[1]Université Laval (*Mineral, Metallurgical and Materials Engineering*), [2]Université Laval (*CR-CHU de Québec*), [3]Plasmionique, [4]Université Laval (*Lab Biomaterials and Bioengineering*)

e-mail: linda-victoria.bonilla-gameros.1@ulaval.ca

Due to the increase of hospital-acquired infections, mainly caused by bacterial adhesion on surfaces, antibacterial (AB) coatings have received increased attention [1]. In this regard, Ag-based AB coatings are of interest since Ag has a broad-spectrum AB action, without risk of bacterial resistance [2]. However, their success as long-term AB coating relies on controlling the release of Ag+ [3]. To reach this goal, plasma processes have emerged as a promising method. Thus, this study focussed on low-pressure (LP) plasma processes to deposit Ag-diamond like carbon (DLC) coatings with tunable release kinetics. Special attention was paid to Ag NPs concentration and oxidation state, known to impact Ag release. To improve and modulate the long-term release, a hydrophobic fluoropolymer was added.

The DLC, Ag-DLC, and AgO-DLC coatings were prepared using a plasma enhanced chemical vapor deposition - physical vapor deposition (PECVD-PVD) reactor. Then, the deposition of the fluoropolymer (CFx) coating was performed using a pulsed plasma polymerization reactor. The composition of the films and the release of Ag+ were assessed. The results showed that by changing the power applied on PVD, Ag content was modulated from 2% to 15%, increasing Ag release up to 20 times. The kinetic release was impacted with Ag oxidation state and top barrier: Ag-DLC showed a slow release reaching a concentration plateau, AgO-DLC a fast continuous-release (better dissolution rate), while CFx barrier displayed a slowly release without reaching a plateau.

In conclusion, by combining these LP plasma approaches, it is possible to tune the release profile of the coating, and so its AB activity. Acknowledgements: The authors thank the Natural Sciences and Engineering Research Council of Canada for financial support.

Ultraviolet (UV) light and oxygen act on several materials as degrading agents. In polymers, this action may generate irreversible changes, which demand total or partial replacement of polymeric products. A simple way of prediction of their degradation level could help the users of this products. Thus, polypropylene samples were coated with thin organosilicone film, to investigate the discoloration mechanism and the potential of the coating as an UV colorimetric sensor. The samples were submitted to Plasma Enhanced Chemical Vapor Deposition (PECVD), in an atmosphere with acetylene, oxygen, and hexamethyldisiloxane (40:20:40), and total pressure of 23.0 Pa. Radio frequency of 13.56 MHz was applied to the sample holder with power of 40 W for 30 min, leading to an amber color coating, characteristic of double conjugated bonds. Subsequently, the samples were exposed to UV-C light until 42 hours, monitored every 3 hours. The films showed a gradual color change and became colorless after 30 hours of exposition. Ultraviolet-Visible Spectroscopy (UV-Vis), Fourier Transform Infrared Spectroscopy (FTIR), Surface Plasmon Resonance (SPR) and image analyses of photography by Hue-Saturation-Lightness (HSL) were used to characterize the samples along photodegradation time. The morphology before and after this process was analyzed by Scanning Electron Microscopy (SEM), and thickness and roughness were measured by profilometry. While HSL and visual inspection could follow the film color changes until 30 hours, UV-Vis and SPR results showed that the degradation kinetics can be well fitted by pseudo-first order model until 42 hours. At this exposition time, the films turned on rougher with a heterogeneous surface. The supposed degradation mechanism is associated with double and triple bonds braking and silicon consumption, followed by atmospheric oxygen incorporation.

e-mail: masoud.shekargoftar.1@ulaval.ca

Antibacterial (AB) coatings are essential for preventing, controlling and managing the spread of infectious diseases, particularly in medical devices [1]. Among the different AB strategies, metal oxide coatings appear as a promising approach, since metal nanoparticles are known for their AB actions [2]. Plasma-enhanced chemical vapor deposition (PECVD) is a well-established technique used to deposit highly adherent metal oxide coatings [3]. In this study, the effect of deposition parameters on the overall properties TiO2 coatings was investigated.

The coatings were deposited using a PECVD330 reactor (Plasmionique Inc.), with Ti-isopropoxide utilized as the source of titanium (Ti). Two working gases, Ar and N2, were used, and the depositions were performed at different pressures and powers. The in-situ plasma composition was analyzed by optical emission spectroscopy (OES). The coatings topography, hydrophilicity, and surface composition analyzed by atomic force microscopy (AFM), water contact angle and X-ray photoelectron spectroscopy (XPS), respectively. OES results evidenced the presence of Ti ions inside the plasma discharge. AFM and water contact angle results showed that the coatings were uniform and hydrophilic, independent of parameters and gases. XPS results evidenced the impact of the working gas. Indeed, with Ar gas 16% of Ti were detected while only 12% with N, but all displaying the expected stoichiometric composition of TiO2. In conclusion, TiO2 coatings with tailored composition were effectively deposited by PECVD. Future works will be to assess stability, cohesiveness, AB and biocompatibility properties of the coatings.

Helium (He) is one of the gases commonly used as the carrier gas to generate cold atmospheric pressure plasma jets (CAPPJs). In this work, it was found that most of the heating of a He CAPPJ comes just from the expansion of the He gas into ambient air. This was observed by measuring temperature (T) values directly in the gas stream and also with the He flow impinging on a copper plate, comparing the conditions with and without discharge ignition. It was found that the T values increased as the distance from the gas outlet was enlarged, even without discharge ignition. Some works have reported a depression in agar substrates when He is the working gas, and it is flushed at high speeds. In a recent experiment in our labs, argon (Ar) and He were flushed with and without discharge ignition on agar substrates at a flow rate of 2.0 l/min. The results have shown that the depression on the material surface occurred only when using He. Curiously, such depression was observed not only when the plasma jet was ignited but also when there was only the gas flow. This indicates that such depressions may be linked to the T value of He gas impinging on agar substrates. In another experiment in our labs, a He CAPPJ was applied directly onto BEAS-2B cells to evaluate the possible cytotoxic effect of the same plasma jet on epithelial cells derived from the human lung tissue, which is known to be sensitive to intense gas flows. The BEAS-2B cells were exposed to the CAPPJ for 5 min at two working distances (5 and 10 mm) between the plasma outlet and the cells. It was expected to obtain larger cell viability for the larger distance, but the opposite was observed. This result may also be linked to the T increment of the He CAPPJ as distance increases. The correlation between increase in T due to the He flow alone and the biological observations will be discussed.

Silicone T-tube prostheses (STP) are the most frequently used alternative for airway rehabilitation of patients with tracheal stenosis, whose prevalence increased significantly due to COVID-19 pandemics. The formation of microbial biofilms inside STP can lead to degradation and clinical complications [1]. Cold plasma jet (CPJ) is a promising technology for biofilm control, due to the reactive oxygen and nitrogen species generated and low cytotoxicity. In this study, the antimicrobial activity of CPJ was analyzed against multispecies biofilm formed on STP specimens. The biofilms were formed by Candida albicans (ATCC18804), Staphylococcus aureus (ATCC 6538), and Pseudomonas aeruginosa (ATCC 15442) (n=9) at 37°C for 48 h at 120 rpm, under aerobiosis. The biofilms were treated for 5 min by helium-CPJ at 0.5 cm of distance, 31.0 kHz frequency, 17.2 kV voltage amplitude, and 2.0 SLM gas flow. After plasma exposure, the samples were sonicated in sterile saline solution. Finally, the suspensions were serially diluted and plated in specific agar to determine viable cell counts (CFU/mL). Cytotoxicity against BEAS-2B cells was also assessed. 40,000 cells were plated using LHC-9 medium at 37 °C and 5% CO_2 (n=12). The cells were exposed to the products of CPJ generated inside the T-tube. The plasma treatment was performed for 5 min, using the same parameters adopted for antimicrobial activity assays. After 24h, the cell viability was evaluated using the MTT reagent. The resulting density was measured at 570 nm. Non-exposed control group was included. CPJ showed antimicrobial efficacy against C. albicans and S. aureus cells in the multi-species biofilm (Mann-Whitney, p= 0.0001). The reduction of P. aeruginosa cell count was not statistically significant. The protocol was non-cytotoxic to BEAS-2B when CPJ is generated inside the T-tube.

The reactive plasma technique is often employed to activate the surface of materials chemically and physically. In this study, plasma treatment processes were used in order to modify graphene and graphene/carbon nanotube electrodes. The plasma parameters herein investigated were plasma intensity, partial pressure of oxygen, and reaction time. The surface morphology, the generation of C-C bond defects, surface chemical composition, interfacial free energy, and electrochemical properties were analyzed for the Multilayer Graphene (MLG) electrodes. The treatments effectively promoted the MLG electrode’s surface activation, considering the results obtained, which showed a dependence on those plasma treatment variables. The results suggested that plasma treatment variable adjustments can be used to modulate specific surface properties with potential applicability in electrochemical sensors and supercapacitors. High capacitances were obtained for MLG electrodes treated in the intense plasma region for the longest time experimented (180 s). They were in fact 1450% higher than the non-treated MLG electrode. Supercapacitors composed of MLG and Carbon Nanotubes (CNT) electrodes were exposed to CO2 plasma treatment. These hybrid supercapacitors exhibited a specific capacitance of up to 256 mF cm-2 (603 F g-1), 260% greater than that obtained before the treatment (97.2 mF cm-2). Outstand capacitance retention after 1000 cycles, and high energy and power densities (24.03 μWh cm-2 and 2.16 mW cm-2) were observed for supercapacitors assembled using plasma-treated electrodes.

Plasma in the modification of natural polymers

Renata Antoun Simão[1]

[1]Universidade Federal do Rio de Janeiro (*Programa de engenharia metalurgica e de Materiais - PEMM*)

e-mail: renata@metalmat.ufrj.br

Due to the variety of species that can be formed in the plasma, as well as different techniques available for plasma application, plasma is being widely used for starch modification. The starch industrial sectors search for economically feasible and easy to implement solutions for modification of starch granules aiming the reduction of gelatinization temperature and stability of the starch paste. Plasma activated water (PAW) isa relatively new field in plasma field and can be cheap and easy to be implemented in large scale. PAW generates no residues and as it contains reactive oxygen and nitrogen species (RONS), can induce oxidation and pH change in the liquid. Long-lived species, such as H2O2, NO2 –, NO3 –, and O3 are observed in the PAW within weeks. Although the numberof papers dealing with the different uses of PAW increased significantly recently, little is being made in the direction of observing materials properties when immersed in PAW. This presentation will show examples of applications of PAW in the modification of lignin, starch and other polysaccarides by plasma, including the formation of nanoparticles.

Antimicrobial hybrid films produced by plasma assisted deposition techniques

The COVID-19 pandemic has mobilized the world scientific community to find mechanisms to mitigate the human vulnerability to the transmission of diseases by infectious microbes. In this scenario, the development of surfaces with antimicrobial properties is widely examined to avoid the fomite mode of transmission of infectious viruses and bacteria [1,2]. Therefore, this work presents the use of deposition techniques PVD-MS [3] and PACVD to produce an antimicrobial hybrid film, composed of SiO2 and Cu, on an austenitic stainless-steel surface. For this purpose, a Direct Current Plasma reactor with a magnetron sputtering device was designed, constructed, and tested. Then, deposition experiments were performed with variation of the target voltage parameters, sample holder voltage, and silicon precursor cycle. The objective was to investigate the effect of different plasma parameters on the physicochemical properties of the coatings, while sustaining the potential antimicrobial attribute. Then, the films were characterized in terms of chemical composition, thickness, topography, microstructure, and crystalline phases, in order to associate the physicochemical characteristics to deposition parameters. As a result, most of the produced coatings are composed of a significant amount of metallic copper and copper oxide (antimicrobial agents), homogeneously distributed as sub-micrometer spherical particles. In addition, they presented good adhesion quality.

The development of new technologies for water treatment has been motivated nowadays due to the growing need to obtain clean water all over the world. Cold atmospheric pressure plasma jet1(CAPPJ) is a technology that can be applied very efficiently to degrade organic pollutants present in water from industrial processes. In this type of discharge, the application of high electric fields can excite, ionize and dissociate molecules of a gas, producing a very large number of reactive species containing oxygen and nitrogen in the atmosphere surrounding the plasma. These formed reactive species can interact with a material close to plasma2. The objective of this research was investigated the effects of the application of cold atmospheric pressure plasma jet in the degradation of methylene blue dye in aqueous médium using argon as carrier gas. It was possible to evaluate the effects of several parameters such as volume, concentration, pH of the solutions and different irradiation times (60-12000 s). With the use of a UV-visible spectrophotometer was evaluated the degradation of methylene blue dye. An increase in the percentage of methylene blue dye degradation occurred with longer plasma jet application time and, while the pH of the untreated solution was close to neutrality, after treatment the solution acquired an acidic pH. Through the analysis of total organic carbon (TOC) it can be observed that the amount of organic carbon decreased with the time of plasma treatment. The results obtained showed that the degradation of methylene blue dye was strongly dependent of the irradiation time.

Characterization of silicon thin films using Tris(dimethyl amino)silane by Plasma Enhanced Atomic Layer Deposition

Danielle Cristina Fernandes da Silva Spigarollo[1], Elidiane Cipriano Rangel[2], Nilson C. Cruz[1]

[1]Universidade Estadual Paulista (*POSMAT*) , [2]Universidade Estadual Paulista (*Control and Automation Engineering*)

e-mail: daniellespigarollo@gmail.com

Thin silicon films deposited by plasma enhanced atomic layer deposition (PEALD) have been extensively studied since they present a variety of high aggregated value applications in microelectronics devices and as protective films for corrosion protection [1, 3]. Amino silane precursors has been used to produce these films by PEALD, but Tris (dimethyl amino) silane (TDMAS) has been reported as a difficult precursor for production of this type of film, due to the high energy required to breakdown the third dimethyl group. In this work, it was investigated the paths of film formation in PEALD using O2 plasma for oxidation of the thermally deposited layers from TDMAS. It was evaluated the influence of the atmosphere composition, on deposition and oxidation stages, on the film properties. The chemical structure and composition of films was analyzed by Infrared Reflection-Adsorption Spectroscopy, Energy Dispersive Spectroscopy and X-ray photoelectron spectroscopy. Corrosion resistance was determined by electrochemical impedance spectroscopy and polarization tests. The results revealed the presence of SiOx, as well as Si-CH3 and Si-N impurities preserved from the precursor' s structure [2, 3]. The atomic proportion of the elements indicated the formation of SiO2, but also confirmed the presence of organic impurities, like CH3. It was observed a uniform interface along the entire film surface that increased the resistance of carbon steel against corrosion in saline environments.

Acknowledgements:The authors would like to thank LNNano/CNPEM for the use of PEALD.

SiO_x films are versatile materials that find numerous applications in different fields such as optical coatings, corrosion protection, and food and pharmaceutical packaging. One of the most commonly used methods for depositing SiO_2 films involves the use of hexamethyldisiloxane (HMDSO) monomer at atmospheric or low pressure. However, this work presents an innovative approach that uses a hybrid corona-Dielectric Barrier Discharge system operating at atmospheric pressure. The system continuously treats conjugated activation and deposition processes, with a total discharge power of 570 W at 56 kHz and employs silicic acid ($Si(OH)_4$) solution as the precursor to deposit SiO_2 films on polyamide fabrics. The use of silicic acid as a cheaper replacement for HMDSO is an attractive alternative that reduces costs without compromising the quality of the deposited films. To analyze the composition and morphology of the deposited films, Fourier Transform Infra-Red (FTIR) spectroscopy and scanning electron microscopy were used, respectively. FTIR analysis revealed noticeable Si-O stretching peaks at 1024 and 1085 cm^{-1}, which became substantially more intense after the plasma deposition process, indicating a higher concentration of nano-silica on the surface. Scanning electron microscopy showed significant erosion on the surface of air plasma-treated fabric and confirms the efficient coating processes of nanostructured SiO_2 films. This innovative approach could have significant implications for the development of more efficient and cost-effective methods for depositing SiO_2 films in different applications, with potential benefits for textile industries.

Titanium dioxide has attracted great attention in the field of environmental purification since it is photocatalytic under ultraviolet light. The photocatalytic efficiency and energy required for inducing the process still represent drawbacks inhibiting the diffusion of the process. In this study a one-step low-pressure plasma methodology for the immobilization of TiO2 particles on silicon-based thin films was investigated. It evaluated the effect of plasma excitation power on the incorporation of TiO2 particles into the silicon-based structure. Substrates were attached at the upper electrode of a capacitively coupled reactor while 0.8g of TiO2 power was spread in the lowermost one. The plasma atmosphere was composed of 20% HMDSO and 80% Argon at a total working pressure of 4.0 Pa. Plasma was ignited and maintained for 3600 s by application of a radiofrequency signal to the lowermost electrode where the TiO2 precursor was placed. The effect of plasma excitation power on the molecular structure and its chemical composition was determined using infrared spectroscopy. Organosilicon to silica films was deposited from varying deposition power in both deposition processes: PECVD and PECVD associated with sputtering. However, titanium was detected in the structures prepared by the hybrid methodology. The proportion of titanium and particles incorporated in the silicon-based matrix was observed to be dependent on the plasma excitation power. An overall decrease in film thickness was observed with increasing power for PECVD and PECVD associated with sputtering deposition. The presence of Ti in the plasma atmospheres changes the plasma deposition mechanisms, thus affecting the deposition rate, roughness, and wettability of the film. Interpretation is proposed in terms of the plasma activation degree and sputtering yield dependencies on the excitation power.

e-mail: miguelrubida@gmail.com

DLC films are amorphous carbon films consisting of sp^2 (graphite) and sp^3 (diamond) hybridizations. These films have been the focus of recent research due to their low coefficient of friction, and high hardness. However, due to its problem of poor adhesion on metallic substrates and low thermal stability, some alternatives have been developed to overcome that problem, for instance, the doping of DLC films with different elements [1]. This work aims to develop and characterize a Si-doped DLC with hexamethyldisiloxane as the Si propellant, in comparison with conventional DLC tribological and structural properties. Plasma depositions were carried out using a pulsed-DC power supply. Plasma ablation cleaning was performed with a gas mixture of 80%Ar-20%H_2 for 1h. DLC and Si-DLC films were deposited with a gas mixture of 90%CH_4-10%Ar, and 90%CH_4-8%Ar-2%HMDSO respectively, with a gas flow of 30sccm, for 2h. Raman and FTIR spectroscopies were performed to analyze the structures of the films, while fixed ball wear tests with a load of 8N, rotation of 158rpm, and different sliding distances were performedto evaluate the tribological properties of the films. Inspections of Raman spectra reveals that the ID/IG ratio decreased with the presence of Si on DLC, indicating a higher presenceof sp^3 hybridizations and FTIR has indicated the bonding of carbon with silicon. Regardingthe tribological properties of the film, Si-DLC film has presented a lower wear volume, due to the stabilization of sp^3 hybridization. However, the coefficient of friction of the DLC filmhas presented lower when compared to Si-DLC, due to a different wear mode proportionedby this film. Doping the DLC film with silicon from HMDSO has proved itself successfulsince the tribological properties of the film are better than conventional DLC film.

e-mail: jadeh.rede@gmail.com

In this study, we developed a computational routine for theoretical curve fitting of experimental transmittance data of thin films based on the joint density of states (JDOS) [1] model and using the parabolic band approximation for semiconductors. The routine takes experimental transmittance data as input and outputs the best-fit theoretical curve, along with corresponding thin film parameters such as thickness, refractive index, and band-gap energy. Furthermore, this routine incorporates the ability to describe subgap absorption and correct for the effects of film roughness on the transmittance data. To demonstrate its capabilities, we applied the routine to experimental transmittance data of thin films grown by sputtering, including gallium nitride (GaN), aluminum gallium nitride (AlGaN), titanium dioxide (TiO2), and tungsten oxide (WO3), which are of significant interest in various applications such as optoelectronics, catalysis, and energy storage. The obtained results showed good agreement between the theoretical curve and the experimental data for all the materials tested. The thin film parameters, including the thickness, refractive index, and band-gap energy, were consistent with values reported in the literature. Moreover, the subgap absorption and roughness correction also contributed to better agreement between theory and experiment. In summary, our proposed computational routine provides a practical and reliable method for determining thin film parameters and comparing films made of different materials through theoretical curve fitting of experimental transmittancedata of thin films.

e-mail: dark.snake.br@gmail.com

This work presents the polymerization of permethrin (15%) based monomers on polyamide fabrics using dielectric barrier discharge (DBD) to enhance insect-parasite repellency functionalities in polyamide fabrics. Before the polymerization process, the polyamide fabric was activated by DBD discharge using a plasma dosage of 2841 W. min. m^{-2}, operating at 23 kHz with a voltage amplitude of 12.5 kV in atmospheric pressure. After that, the polymerization process was initiated by injecting permethrin into the system while maintaining the operational parameters used in the activation process. The non-activated and activated polyamide fabrics were measured for static and dynamic contact angle, which showed a variation from 120° (non-activated) to 34° (immediately after plasma activation).The chemical structure of the synthed permethrin was evaluated by Fourier Transformed Infrared (FT-IR) spectroscopy to confirm the polymerization (deposition) of permethrin on the fabric surface. It was possible to observe that the 648 cm^{-1} bands were associated with the asymmetric vibration of the C-Cl bonds, but the most significant change occurred at 1045 cm^{-1}, which was associated with the cyclopropyl group vibrations. Field Emission Scanning Electron Microscopy (FESEM) analysis was used to evaluate the possible degradation of the fabric surface when exposed to plasma activation and the homogeneity of the permethrin coating in the fibers after the polymerization. The Energy Dispersive Spectrometer (EDS) was used to confirm the polymerization and the distribution of permethrin in the fabric. The study found that a tested repellent showed 100% efficacy against Aedes aegypti, even after undergoing ten washing cycles.

The carbon nanotube is one of the known carbon nanostructures with attractive electrical, thermal, and mechanical properties for various applications. For this reason, the use of these carbon nanostructures in products has been growing in several areas of activity. On the other hand, these products with nanostructures will be at some point discarded in the environment and may have the interaction of nanostructures with biological systems and generate toxicological effects. Thus, it is important to study the ecotoxicity of these carbon nanostructures. This work aims to study the ecotoxicity of multi-walled carbon nanotubes (MWCNTs) obtained by the Plasma Enhanced Chemical Vapor Deposition (PECVD) technique on the algae *Raphidocelis subcapitata*, bacteria *E. Coli*and *S. epidermidis*, found in the environment. The MWCNTs were grown on the nickel substrate with the precursorgases of methane (CH_4), H_2, and Ar at a total gas pressure of 1.50 Torr, with 700 V for 15 minutes. The carbon nanotubes were characterized by Raman spectrometry, high-resolutionscanning electron microscopy (SEM), and transmission electron microscopy (TEM). The aquatic toxicity test used algae of the species *Raphidocelis subcapitata*, in concentrations of 0.1 to 100 mg/L of MWCNTs. The effect of antibacterial activation was used on strains of *E. Coli*and *S. epidermidis*. The material obtained showed a Raman spectrum with D, G, and 2D bands, characteristic of MWCNTs. The images obtained by SEM and TEM show the nanotubes and the multiple walls are observed. The algae growth inhibition test with commercial MWCNTs showed an $EC_{50}$of 0.7191 mg/L and the MWCNTs obtained by plasma showed an $EC_{50}$of 9.316 mg/L. Microbial tests show that MWCNTs obtained from plasma have no antibiotic effect on the studied bacteria. The results show that the MWCNTs obtained from plasma have low toxicity when interacting with biological systems.

Effect of cold atmospheric argon plasma jet treatmenton titanium surface wettability and protein adsorption

A wettability of surfaces is a key property that affects their biocompatibility and interaction with biological systems [1, 2]. Plasma treatment can modify the wettability of surfaces by adding polar functional groups, but these changes may not be stable over time [3]. We exposed titanium surfaces to an argon plasma jet produced and measured by standard methods. We evaluated the wettability of titanium by measuring the contact angle and calculating the surface free energy and the interfacial energy for albumin and fibrinogen proteins. We also investigated the effect of aging time on the wettability of the treated surfaces. The plasma jet reduced the contact angle of titanium and this effect persisted for 7 days. The surface free energy and the polar component increased after plasma treatment, indicating an increase in hydrophilicity. The interfacial energy for albumin and fibrinogen decreased after plasma treatment, suggesting an improvement in protein adsorption. Our results demonstrate that argon plasma jet can effectively modify the wettability of titanium and enhance its biocompatibility. This technique has potential applications in biomaterials and implantology.

Head and neck cancer is public health problem worldwide with a prevalence of 1.1 million cases annually [1]. Chemotherapy drugs can cause oral mucositis as a side effect of the drug toxicity. Oncological patients with oral mucositis usually present pain and injury which can enhance the risks of infection [2]. Non-thermal plasmas have stood out for their promising effects in the treatment of wounds [3]. This study aimed to evaluate the action of home-made prototype of cold atmospheric plasma jet (CAPPJ) in the healing of oral mucosa wounds in rats underwent to chemotherapy. This screening study was performed with male rats (*Rathus norvegicus*), which received intramuscularly doses of the chemotherapy drug 5-Fluoruracil (5-FU, 30 mg/kg), followed by oral mucositis induction in the vestibular fornix, with the aid of sterile filter paper soaked in 50% acetic acid. For the treatment, the animals were anesthetized and the wound treated for 2 consecutive days with CAPPJ with helium gas (He) in a time of 5 min at a distance of 1.5 cm. Control group was not exposed to the plasma jet. Images of the vestibular fornix were obtained after 3, 7 and 14 days of the oral mucositis induction (5 per group), followed by the measurement of the injured area in the Software Image J and statistical analysis of the data. Reduction of the injured area was observed after 14 days, with 50.00% reduction for the control group and 78.95% for the CAPJ-treated group. A statistically significant difference was observed between the control (untreated) group after 3 days and the plasma-treated group after 14 days ($p=0.03$; One-way ANOVA, followed by Turkey''s multiple comparison test), with the average of the injured area of 20 mm2 for the control group and 4 mm2 for the treated group. These findings demonstrate the promising capacity of CAPPJ with He gas for treatment of the oral mucositis.

Face filter respirators are used primarily to prevent the spread of airborne pathogens. The fact that face respirators protect the mouth and nose, prevents the contact of contaminated hands with the nasal and oral mucous membranes. The sterilization of this material must eliminate pathogens transmitted by contact with the skin and hands. In a previous work, it was demonstrated that low pressure plasmas, established from citric acid solution vapor diluted with O2 and N2 (13.56 MHz 100 W), promoted effective disinfection of mask fabrics with fungi. In this work it was proposed to evaluate the effect of low pressure plasma on the bacterium Staphylococcus aureus (S. aureus) ATCC 25923. This bacterium is the main contaminant of the skin and is involved in medium and high severity infections. Plasma was generated by applying a DC voltage in a vapor environment of citric acid diluted in isopropyl alcohol solution. Samples treated on positively and negatively polarized electrodes were investigated. Preliminary results indicated that only citric acid vapor was not able to eliminate S. aureus from the samples. Only for one polypropylene sample, a small decrease in the amount of bacteria present after exposure to citric acid vapor was observed. The results indicate that plasma can be a real possibility for disinfecting face respirators for pathogens transmitted by interpersonal contact.

Effect of multicomponent oxide coatings obtained by PEO on the electrochemical properties of commercially pure titanium for biomedical use

The inflammatory responses of human body reduce local pH as reaction against supposed infection. Ti implants are submitted to this acidification which can develop pitting over them. This type of degradation is undesirable because it allows metal ions to diffuse through the body and reach levels of toxicity [1]. One way to reduce the possibility of corrosion of an implant is to increase the resistance of its protective oxide film against chemical attacks [2]. In previous studies, zirconium and tantalum have demonstrated positive contributions to increased corrosion resistance in titanium alloys [3]. The conditions experienced by an in vivo implant are complex to reproduce, but a preliminary in vitro evaluation of the corrosion suffered by a biomaterial seems reasonably interesting. This work studies the electrochemical behavior of multicomponent oxide film obtained by plasma electrolytic oxidation with deposition of Zr and Ta oxides on a commercially pure titanium matrix, in a simulated environment of inflammation.

e-mail: luciana.rossino@fatec.sp.gov.br

Boriding is a thermochemical treatment that involves boron diffusion on the metal surface and is an effective method to improve the surface properties of metals [1,2]. This work aims to study the effect of the plasma boriding treatment using solid paste at a lower temperature and treatment time compared to the traditional method on the boride layer formation and wear resistance in different types of metal. Plasma treatment was performed using a DC-pulsed source at 750°C for 6 hours in an atmosphere of 40% N_2, 40% H_2, and 20% Ar at 500 sccm of total gas flow. The solid paste composed of boriding agent Ekabor2®, $Na_2B_4O_7$, and ethyl alcohol was sprayed on samples of Ti6Al4V, AISI 1020 steel, and SAE 304 stainless steels. The samples with and without treatment were characterized by microhardness, metallography, and microwear test by fixed ball. The formation of the boride layer was observed in all treated samples without significative variation in hardness compared to base metal due to the thinner formed layers. The formed layer, even thin, was efficient in increasing the wear resistance of all treated materials, being more effective for stainless steel 304. It was observed that the type of substrate influenced the thickness and wear resistance of the treated material, whose boron was more effectively diffused in the titanium alloy, while the FCC structure present in the stainless steel favored the diffusion for the ferrous alloy compared to with the characteristic BCC structure of 1020 steel. It is concluded that the plasma boriding treatment using solid paste was efficient in the boride layer production that increased the wear resistance of the studied metals, whose type of substrate significantly influenced the characteristics of the produced layer.

The work of health professionals entails physical, chemical and biological risks that can compromise their integrity and well-being. To minimize biological risks, face masks play a key role. The sterilization of these respirators has important implications for disposal, requiring reuse and recycling. In a previous work it was demonstrated that low pressure plasmas, established from citric acid solution vapor diluted with O2 and N2 (13.56 MHz 100 W), promoted effective disinfection of mask tissues, demonstrating the potentiality of this new sterilization approach. In this work, the same plasma composition was used in order to evaluated the effect of the plasma excitation power, on the disinfection of N95 mask fabrics (polystyrene and polypropylene) contaminated with fungi Saccharomyces cerevisiae ATCC 9763. Contaminated fabric samples were positioned on the grounded electrode (topmost) of a capacitively coupled reactor. All the disinfection experiments were conducted for 10 min in atmospheres containing 50% of citric acid solution's vapor, 25% of O2 and 25% of N2 at a total pressure of 9.3 Pa. Plasma was ignited by application of radiofrequency signal to the topmost electrode. It was investigated the effect of the plasma excitation power, which was varied from 100 to 300 W, on the properties of the fabric (fibers integrity and wettability), on the fungal growth and on the number of Clonies Forming Unit (CFU). An effective sterilization was observed for polypropylene, while for polystyrene it suffered a fungistatic action. This result was observed in the powers of 150 and 300 W. Despite disinfection efficiency, the plasma excited with 100 W showed the best effective result. Tests with lymphocyte cultures demonstrate that plasma in masks does not generate toxic residues. The evaluation of the results indicates that the plasma treatment can be a new option in the sterilization and reuse of the facial respirators. Since the power to be used should be better investigated.

Effect of the Plasma Power on Lower Electrode on Disinfection of N95 Respirators

Sterilization of face filtering respirators has important implications as one considers their disposal, the necessity of reuse by scarcity and the recycling of pieces used in high contagious environments. In a previous work it was demonstrated that low pressure plasmas, established from citric acid solution vapor diluted with O2 and N2 (13.56 MHz 100 W), promoted effective disinfection of mask tissues, demonstrating the potentiality of this new sterilization approach. In this work, the same plasma composition was used in order to evaluated the effect of the plasma excitation power, on the disinfection of N95 mask fabrics (polystyrene and polypropylene) contaminated with fungi Saccharomyces cerevisiae ATCC 9763. Contaminated fabric samples were positioned on the lower electrode of a capacitively coupled reactor. All the disinfection experiments were conducted for 10 min in atmospheres containing 50% of citric acid solution's vapor, 25% of O2 and 25% of N2 at a total pressure of 9.3 Pa. Plasma was ignited by application of radiofrequency signal to the lowermost electrode. It was investigated the effect of the plasma excitation power, which was varied from 100 to 300 W, on the fungal growth and on the number of Colonies Forming Unit (CFU). An effective sterilization was observed for the polypropylene, while for polystyrene it suffered a fungistatic action only in power 150 W. The worst effect on the disinfection of the masks was obtained with a power of 300 W. Aside presenting a good disinfection efficiency, the plasma excited with 100 W presents the best coast-efficiency relation and did not affect the fibers integrity. Preliminary tests on lymphocyte cultures indicate that exposure to plasma does not generate toxic residues. A discussion is needed regarding the effect of low pressure plasma power on fungal cultures. Acknowledgment FAPESP grant #2022/08020-0.

Enhancing Coating Adhesion on Metallic Surfacesthrough Cold Plasma Treatment

Augusto Adami Vidal[1], Letícia Alves da Costa Laqua[2], Isabeli Martins Longaretti[3], Aloisio Nelmo Klein[1], Rodrigo Perito Cardoso[4]

Corrosion prevention is often achieved by applying coatings, including polymeric coatings in various forms, such as liquid coatings, powder coatings, or solvent-based coatings, as well as paints, which are typically liquid coatings that contain pigments and binders. However, a critical characteristic that directly influences the coating's performance is its adhesion to the substrate. Our preliminary study aims to enhance coating adhesion by subjecting metallic surfaces - low-carbon steel and aluminum - to cold plasma treatment, which uses ionized gas to remove organic and inorganic contaminants from the surface, leading to a more active surface because of the increase in surface energy. In order to achieve our objective, a cold plasma reactor was employed with the following operating parameters: V = 700 V; P = 1 Torr; t = 10 min of plasma treatment; and a gas mixture of hydrogen at a flow rate of 40 SCCM and argon at 160 SCCM. Rectangular steel and aluminum plates, measuring 90 x 60 mm, were treated at the cathode using the previously mentioned reactor. Following plasma treatment, both treated and untreated samples were coated with a layer of polyurethane varnish applied using a 100 µm spiral bar coater. In accordance with the ABNT NBR 11003, an adhesion test was then performed. After the test a salt solution of 50 g/L was sprayed over the grid pattern described in the standard to evaluate the corrosion resistance. The results showed that the adhesion behavior of the aluminum samples was significantly improved after treatment, whereas the adhesion of the steel samples did not exhibit the same level of improvement. Furthermore, when it comes to corrosion, aluminum samples do not present significant differences between the treated and untreated samples. However, at steel samples, when more adhesion occurred, less corrosion spread under the varnish was observed.

Evaluation of the antitumor effect of NaCl and Ringer lactate solutions treated with atmospheric pressure plasmas on the in vitro viability of melanoma cells.

Diego Verduíno das Neves[1], Daiane Matos de Lima[1], Maria Vitória Faustino Fragoso[1], Amanda Dias da Rocha Lima[1], Breno B. Ferrari[1], Kaique Gomes Hergesel[1], Elaine C de Oliveira[1], Elidiane Cipriano Rangel[2], Nilson C. Cruz[3]

e-mail: diegoverduino@hotmail.com

Recent literature presents encouraging studies on direct and indirect application of atmospheric pressure plasmas (APP) for the treatment of superficial tumors. The plasmas have been directly applied on tumors or to saline solutions, which are subsequently applied to the tumor mass. Melanoma is one of the most common types of cancer in the world. Particularly, in Brazil it corresponds to about 30% of cases registered in the country annually. In this scenario, the objective of this work was to evaluate the effect of sodium chloride 0.9% NaCl and Ringer lactate solutions exposed to APP on B16F10 murine melanoma cell line in two- and three-dimensional cultures. The solutions were exposed to argon plasmas for 30, 45 and 60 min and sterilized in 0.22 μm filter. After the treatments, the B16F10 cells and the control cell line L929 (murine fibroblast) were incubated for 30, 60 and 120 min with the pristine and plasma treated solutions. Cell viability by MTT has shown that the treated solutions significantly reduced the viability of B16F10 cells when compared to untreated solutions. After the experiments, the solutions were frozen and tested again. It has been observed that even 75 days after the plasma exposure, the solutions were still able to continue reducing B16F10 cell viability. The evaluation of the type of cell death showed that the different solutions induced both cell death by apoptosis and necrosis, positive for Annexin V and/or propidium iodide. As assessed by flow cytometry, the treatments also interfered with the expression of surface molecules, such as PD-1 and PDL-1, responsible for the suppression of the antitumor immune response. Regarding the 3D culture, the capacity of the liquids to reduce the of the spheroids in vitro was evaluated, comparing with the liquids treated on the same day. In conclusion, liquids treated with APP and frozen have presented an effect on tumor cells even after 180 days of treatment. Acknowledgement Fapesp process 2020/06448-7.

Exometabolomics of fibroblast cells on titanium surface modified by cold atmospheric plasma.

e-mail: marcospaulo.viana@hotmail.com

The use of cold atmospheric plasma (CAP) can be use to improve the titanium surface functionality for induces cells to synthe adhesion proteins and activate metabolic pathways [1][2]. Both are crucial for ensuring implant quality and healing; However, it is unclear which metabolic pathways CAP activate. Therefore, our objective is to evaluate the exometabolomics of fibroblasts on CAP-modified titanium surfaces. Titanium discs were polished and treated with CAP at 15kV,600Hz, and a He flow rate of 1 L/min for 15 minutes. The discs were characterize for wettability(sessile drop), roughness profile (AFM), and chemical composition (XPS). 3T3 cells, murine fibroblasts, were cultured in DMEM with 10% fetal bovine serum for cell viability tests (MTT). Additionally, exometabolomic analysis used the protein S precipitation protocol for NMR. We observed that CAP increased the OH-bonds, making the titanium surfaces more hydrophilic (14°±2.2 vs. 59°±1.8, $p<0.01$) andreduced surface roughness (3.6±1.01 vs. 7.5±2.05, $p<0.01$). On the treated surfaces,cellsincreased their viability (0.61±0.1) after 24 hours. The changes in glutamine metabolismconfirmed by cell proliferation, as CAP prefers the aerobic pathway for more efficient energy production and cell adhesion to titanium [3].

Friction and wear between steel test bodies using RF plasma-deposited diamond-like carbon flakes dispersedin oil.

Cauê de Souza Coutinho Nogueira[1], Yutao Xing[2], Dante Ferreira Franceschini[2]

[1]Universidade Federal Fluminense (*Departamento de Física*) , [2]Universidade Federal Fluminense

e-mail: cauenog@gmail.com

Diamond-Like Carbon (DLC) coatings have been extensively used in the industry to reduce friction and wear.[1] Hydrogenated amorphous carbon (a-C:H) films deposited by plasma discharges on hydrocarbons such as methane and acetylene are the most commonly used films. Recently, it was reported that the coefficient of friction between DLC-coated surfaces can be altered by the presence of DLC particles resulting from the wear of the coating in the lubricant oil.[2] The aim of this study is to investigate the coefficient of friction between steel surfaces coated or not with DLC, using lubricating fluids with an additive based on DLC flakes. The DLC flakes were prepared by depositing DLC films, by RF glow-discharge plasmas (50 mTorr pressure, -300 V self-bias) onto commercial vacuum pump oil, which were added to mineral oil, to form the lubricating fluid. The samples obtained were analyzed by Raman spectroscopy, showing spectra with parameters characteristic of DLC. FEG-SEM images of the samples showed that the deposited film broke into flakes ranging from hundreds of nm to tens of µm. Tests were carried out to determine the coefficient of friction (COF) between steel-steel pairs and DLC-coated steel pairs with and without lubrication, with a normal force of 10 N, for 24 hours. The lubricant mixtures showed a COF reduction compared to pure mineral oil, and the addition of DLC particles to this mixture resulted in a significant COF reduction. The mixture of DLC flakes in mineral oil/vacuum pump oil produced values similar to the DLC against DLC pair, with direct deposition, allowing low friction regimes even in systems that do not allow direct deposition.

Carbon nanotubes (CNT) have been widely used in recent engineering applications due to their excellent mechanical properties, ease of surface modification, and capability of high adsorption level, which makes them able to be used, for example, as an adsorbent agent in water treatment [1]. However, CNT must be functionalized before use to prevent agglomeration and improve chemical interaction. Plasma treatment is a green alternative to the wet chemical process that attends to that need once it is fast and free of solvent process that can provoke CNT surface modification. In the present work, CNT was mixed with urea in the solid state and then treated in 35 W radio frequency plasma, in 1 Torr, for 30 minutes, following the instructions of another work [2]. Three combinations were set to evaluate the gas composition influence on plasma treatment of CNT: treatment with Ar, Ar, and O2, or Ar and N2. Both gas mixtures were done with a partial pressure of 80 % Ar. After treatment, all samples were methanol washed, intending to remove the possible chemically unreacted urea. Characterizations were conducted by Fourier Transformed Infrared (FTIR), Thermogravimetric analysis (TGA), Brunauer-Emmett-Teller (BET) adsorption method, and X-ray Photoelectron Spectroscopy (XPS). The oxygen concentration decreases with the change in the gas composition, and the nitrogen content on the NTC surface is relatively low, independent of the gas composition, with the highest value for sample NTC+Urea_Ar+N2 (0,35 %at.).

Austenitic stainless steel is widely accepted for hydrogen-related application equipments, owing from its low hydrogen embrittlement susceptibility [1]. Here, the first stages of hydrogenation were analysed and compared with the well-known N-expanded austenite. A 4-hour H-cathodic charging at 0.1 A/cm² in 1M H_2SO_4 electrolyte applied to a superaustenitic stainless steel produced a metastable H-expanded phase by interstitial solid solution. The in-situ XRD analysis disclosed two distinct lattice expansions and the eventual return to the pristine FCC lattice in about 1-day time. The two expanded phases showed an strain inversion between crystallographic planes, which has been observed in nitrided austenitic steels [2]. The mechanical behaviour of the modified surface revealed a twofold hardness increase and elastic modulus 17% higher due to the H-inlet, both of them returning progressively to the pristine values while hydrogen diffused out from the material. At a constant indenter load test, the H-charged surface underwent higher indenter penetration during the creep stage of the test. This is consistent with a competitive effect, where the solid solution strengthening overcomes the H-enhanced plasticity in the initial period of hydrogen outgassing.

Modification in photodegradation pattern of polypropylene by coating with PECVD organosiliconthin films

Polypropylene (PP) is a material widely used in the manufacturing of parts for external use, however, this material suffers degradation when exposed to light in the presence of atmospheric oxygen. The degradation occurs by a series of oxidative reactions, which generate an increase in the crystalline domains on the surface, leading to crack formation. The cracks usually follow a parallel disposition pattern and are many micrometers in , these cracks make the material more brittle. Therefore, there is a search for ways to protect the PP from weathering, such as painting the surface of the material. However, the paint layer, despite protecting the material, promotes an aesthetic modification in the parts, which is not always desired. Thus, plasma coating can be a solution to protect PP from photodegradation. The samples were pre-treated with oxygen gas plasma for 5 min at 50W power. Organosilicone thin films were deposited by Plasma Enhanced Chemical Vapor Deposition, for 15, 30, 45 and 60 min, in an atmosphere with a 50:50 mixture of hexamethyldisiloxane and oxygen, with power of 80 W. The produced sample set was exposed to UV-C light in a photodegradation chamber, for the interval of 196 hours. The degradation of the samples was followed by Scanning Electron Microscopy and Fourier Transform Infrared Spectroscopy. The results suggest that the thin film promotes a mechanical anchorage that reduces the dimensions of the cracks formed by photodegradation in the coated PP relative to the uncoated material. This phenomenon occurred in all samples, regardless of the thickness of the films. However, they did not offer photoprotection to the polymer, this was evidenced by the formation of hydroxyl and carbonyl chemical groups, characteristic of photodegradation of the polymeric substrate.

Obtaining Vibrational and Rotational Temperatures in Plasma Microjets by Optical Emission Spectroscopy.

Eduardo Cezar Barbosa de Barros Aragão[1], Bogos Nubar Sismanoglu[2], Marcelo Pêgo Gomes[2]

[1]Universidade Federal dos Vales do Jequitinhonha E Mucuri (*IECT*) , [2]Instituto Tecnológico de Aeronáutica

e-mail: cezaragao@yahoo.com.br

Electrical discharges operating at atmospheric pressure and open environment, call attention due to the great possibility of application, ranging from superficial modifications of materials to biomedical and agriculture applications. Determining the operating temperatures of the plasma jet is important to ensure, among other things, that the plasma jet operates in a way that does not cause unwanted effects when applied [1,2]. MassiveOES is a software developed specifically for the analysis of optical emission spectra of plasma discharges, its objective is to focus on the experimental and scientific challenges that you will encounter during plasma spectroscopy. It is developed in python library by researchers Dr. Jan Vorac and Dr. Petr Synek from Masaryk University in Brno, CEPLANT center, and one of his goals is to obtain rotational and vibrational temperatures from the deconvolution of experimental curves of the emission spectrum of diatomic molecules. The objective of this work was to study the optical emission spectra of argon and helium plasma microjets to determine their vibrational and rotational temperature, using the MASSIVEOS software. It was possible to observe that the rotational temperatures of helium microjets ranged from 320 K to 430 K, thus showing that these kind of microjets can be applied in surface modification of materials of the most diverse natures and characteristics, as well as in medicine and agriculture.

Physical and mechanical properties evaluation ofWC-10 wt.% Co with incorporations of carbon nanotubes via Spark Plasma Sintering

Marcello Filgueira[1], Renan da Silva Guimarães[1], Rafael Delorence Lugon[1]

[1]Universidade Estadual do Norte Fluminense Darcy Ribeiro (*LAMAV*)

e-mail: marcello@uenf.br

The combination of the high hardness of the tungsten carbide with the fracture toughness of the cobalt binder makes the WC-Co composite an important material for the tooling industry. However, the incorporation of structures in order to improve certain properties of this class of materials is the subject of several researches. One of these structures are the carbon nanotubes (CNTs), which are incorporated in several ceramics, alloys, metals, because of their unique properties. This work aimed to evaluate the physical and mechanical properties of WC-Co with the addition of carbon nanotubes, in the amounts of 0.10, 0.25, 0.50 and 1.00 wt.%. As sintering methodology, the Spark Plasma Sintering (SPS) technique was employed. The sintering process occurred under temperature of 1200 ℃ and pressure of 40 MPa, during a period of 5 minutes. The physical and mechanical properties of the studied systems were evaluated in detail, observing the increase of the apparent density, the stability of the Vickers hardness and the increase of the Young’s modulus of the system with 0.10wt.% CNTs - compared to the system without CNTs incorporated - reaching averages of 14.27 g/cm3, 14.96 GPa e 451 GPa, respectively. The fracture toughness increased gradually up to the system with 0.50wt.% CNTs, reaching the value of 12.93 MPa.m1/2.The values of compressive strength and splitting tensile strength also increased progressively to the system with 0.25wt.% CNTs, reaching the averages of 2905.77 e 474.30 MPa, respectively. Considering the results obtained by the characterization techniques, the system with the incorporation of 0.10wt.% CNTs presented the best performance. For the systems with the highest amounts of CNTs, the decrease in the values of the evaluated properties occurred due to the agglomeration of the carbon nanotubes.

Plasma treatment to improve hydrophobicity ofbacterial cellulose.

Teresa Tromm Steffen[1], Alline Araújo I. Rolim[2], Daniela Becker[3], Luis César Fontana[4], Luciana Rosa Leite[2], Danielle Bond[2]

e-mail: teresa.ts@udesc.br

Bacterial cellulose (BC) has attracted attention in recent years, since its easy synthesis and green appeal make it a promising material to replace animal leather in the fashion and textile industry. However, an inherent issue related to BC regards its wettability (contact angle of about 45°). The hydrophilic nature of BC means it is not suitable for wear in conditions where there may be increased humidity, such as next to the human skin, and therefore, cannot be subjected to domestic washing [1]. Plasma treatment is a sustainable alternative to overcome that problem, once is capable to coat the BC surface with hydrophobic films formed through carbon gases [2]. In the present work, bacterial cellulose was synthed using kombucha, following the instructions of another work [3], and subsequently treated by DC pulsed plasma. In the way to evaluate the plasma parameters on the film formation above de BC, four different combinations were set, changing gas compositions (Ar and C_2H_2; or Ar, C_2H_2 and H_2), time (5 or 30 minutes) and polarity time off (2 or 4 µs). Characterizations were conducted by Fourier Transformed Infrared (FTIR), X-ray Photoelectron Spectroscopy (XPS), Scanning Electron Microscopy with Field Emission (SEM-FEG), and Water Contact Angle. For all the treatments, results indicate a carbon film formation on the surface of bacterial cellulose, resulting in an improvement of material hydrophobicity. The best plasma condition (Ar and C_2H_2, 30 minutes, 4 µs of polarity time off) was defined by the highest water contact angle obtained: 102°, in comparison to 33° forthe non-treated BC.

e-mail: fkopresido@yahoo.com

Plasma Enhance Chemical Vapor Deposition (PECVD) is widely used to the growth of Diamond-Like Carbon (DLC) films on surfaces with large areas and irregular geometry. Due to its excellent tribological, mechanical, chemical, properties, etc DLC films are used as a protective coating. And due to great interest in applications technological and medical provide by boron, in this works, it is explored the incorporation of boron into the DLC films by using the enhanced PECVD process. The system was prepared with an additional cathode, placed inside the PECVD reactor, to confine the plasma, and a bubbler, placed outside the reactor, to produce the boron solution. Thus, the boron doped DLC film was grown on Ti-6Al-4V and Si substrates by varying the pressure and voltage. They were varied from 3mTorr to 7mTorr and from 0.7kV to 1.0kV, respectively. Changes in structural, mechanic, tribological and electric properties of the doped DLC film were evaluated. The results evidenced presence of boron in all doped samples. The electric resistance was strongly reduced in conditions of higher pressure and voltage. Our results showed that the pressure and voltage variation resulted in a progressive graphitization of the doped films. Other analyses are in progress.

Production and characterization of $Al_xGa_{1-x}N$ films by reactive dual magnetron sputtering

Isabela Machado Horta[1], Bárbara Souza Damasceno[1], Regiane Santana de Oliveira[1], Argemiro Soares da Silva Sobrinho[1], André Luis de Jesus Pereira[1], Douglas Marcel Gonçalves Leite[1]

[1]Instituto Tecnológico de Aeronáutica

e-mail: isabelah1@poli.ufrj.br

This study focuses on the production and characterization of $Al_xGa_{1-x}N$ films using reactive magnetron sputtering. The films were grown directly on Si (111) substrates using a 4-inch Ga target powered by a 600W RF power supply and a 1-inch Al target powered by a 1kW DC power supply. The liquid Ga target was positioned to directly face the rotating substrate holder at a distance of 90 mm, while the Al target was located at 150 mm from the center of the substrate holder and tilted at a 45-degree angle. A 1:2 Ar/N_2atmosphere was maintained at 5 mTorr, and the substrate temperature was kept at 550°C during the 120-minute deposition process. To ensure uniformity, the substrate was rotated at 6 rpm. Ten samples were grown using different combinations of individual target power for Ga and Al to adjust composition. The composition of the samples was analyzed using energy dispersive spectroscopy, and the thickness was measured using profilometry. X-ray diffraction (XRD) was used to study the crystalline structure of the samples. The deposition rate showed a strong dependency on the target powers, with a greater increase observed for Ga power compared to Al power. The target size and geometry of the deposition chamber, including the different distances and angles between the substrate holder, as well as the different power supply used (RF and DC) and the different sputtering yield of Al and liquid Ga, may explain this difference. The XRD results revealed that all samples exhibited only peaks related to the wurtzite phase, with a stronger c-axis orientation observed for the Al richer samples ($x > 0.24$), which were produced using 30 W on the Ga target. The lattice parameters $a$and $c$decreased with increasing x, with a deviation from linear behavior that could be attributed to the strain on the produced $Al_xGa_{1-x}N$ films.

e-mail: isabella.grinberg@gmail.com

Silver nanoparticles (AgNPs) have been widely investigated due to their antimicrobial activity against several pathogenic microorganisms. This property makes them suitable for a wide range of applications in medical and healthcare products [1]. One promising use of these nanoparticles is their incorporation into textiles to enhance the effectiveness of face masks against microorganisms associated with respiratory tract infections. In this work, AgNPs were deposited on polyamide 6.6 fabrics by hybrid corona-dielectric barrier discharge plasma at atmospheric pressure with a plasma dosage of 1800 $W.min.m^{-2}$at 19 kHz. This process consists of two steps: surface activation in air plasma and AgNPs deposition using an aqueous dispersion of stabilized AgNPs, which is nebulized into the discharge region. Scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) analysis confirmed the AgNPs deposition on the textile surface, showing that plasma processing is an effective technique for AgNPs incorporation on polyamide 6.6 fabrics. Microbiological analysis based on the American Association of Textile Chemists and Colorists (AATCC) 100-2019 test method evaluated the antimicrobial effect of AgNPs on *Staphylococcus aureus*and *Klebsiella pneumoniae*, which are respiratory tract infection-related bacteria. For this analysis, bacterial suspensions were inoculated into untreated (without AgNPs) and treated (with AgNPs) samples. Significant decreases in bacterial counts were detected in textiles containing AgNPs, with reduction percentages up to 74.63% compared to the untreated sample, indicating that AgNPs are a potential alternative for increasing the effectiveness of face masks.

This study investigates the possibility of preparing of $SiO_xC_yH_z$-TiO_2 photocatalytic films in a single step plasma process that combines the plasma enhanced chemical vapor deposition (PECVD) of hexamethyldisiloxane and the reactive sputtering of TiO_2. The samples were prepared in a capacitively coupled reactor fed with hexamethyldisiloxane (HMDSO), O_2 and Ar, at a working pressure of 4.0 Pa. Plasma was ignited by application of radiofrequency signal (150 W, 13.56 MHz) to the lowermost electrode where titanium dioxide powder, P25, was accommodated. Substrates were attached to the uppermost grounded electrode and process time was of 3600 s. It was investigated the effect of the oxygen proportion in the plasma phase on the properties of the films. The results show the formation of organosilicon, silicon oxicarbides up to silicon oxides structures, all containing TiO_2 particulate. The concentration of granular structures increases with the proportion of O_2. Surface free energy decreases with O_2%. All films presented photocatalytic activity under ultraviolet and visible light irradiation but the highest efficiency was attained when irradiated with ultraviolet light (up to 60% of degradation for 90 min of irradiation). Authors thank to FAPESP (Process number 2020/06448-7 and 2017/21034-1) for finatial support.

Stamping with natural dyes and thickeners on plasma-treated fabrics

João Batista Giordano[1]

[1]Faculdade de Tecnologia Ministro Ralph Biasi (*Produção Têxtil*)

e-mail: jbgiordano@uol.com.br

Textile stamping plays one of the main and important roles for the textile chain, because it is one of the most demanding stages and that comes closest to art, where great value is added to the product, with this has been changes and several possibilities arise for process improvement. In the stamping are used thickeners for formulations of pastes that are colored and stamped. In the coloring are used synthetic dyes, which are aggressive to the environment. Thus, in this work we used natural dyes and thickeners that are less aggressive and from sustainable sources. In the preparation of pre-stamping tissues plasma was used which is a unique treatment, in which a large amount of water, chemical agents, energy and process time are consumed. The objective of this work was to stamp on tissues treated with plasma, using thickeners and natural dyes. Natural thickeners of sodium alginate, guar and tamarind were used for formulations of pastes, and colored with natural dyes of annatto and turmeric, then they were stamped on cotton fabrics that were previously submitted to treatment with oxygen plasma for 5 minutes, with a power of 100 W and pressure of 100 mTorr. Then the prints were fixed with steam at 100°C for 40 minutes. then the fabrics were washed with room temperature water to remove the unfixed dyes and thickeners. The results showed that the prints with natural dyes in plasma fabrics were similar to those of conventionally treated fabrics. It was also observed that the natural thickeners had good performance in the stamping, and the sodium alginate thickener, had better results in the sense of ease of removal in subsequent washes. As a product we can get printed fabrics using sustainable sources in addition to using plasma in the pre-stamping preparation, which makes the whole process beneficial to the environment.

Structural changes produced by He plasma treatmenton Hydrogenated Carbon Nanoparticles

Ramon Pinna Brito[1], Cauê de Souza Coutinho Nogueira[2], Dante Ferreira Franceschini[2]

[1]Universidade Federal Fluminense (*instituto física*) , [2]Universidade Federal Fluminense

e-mail: ramonpinna@id.uff.br

In this work, the structural changes caused by He plasma treatment of amorphous hydrogenated carbon nanoparticles were studied. The nanoparticles were produced by RF-dusty plasmas with acetylene as a precursor. The particles were dispersed in acetone and dripped on a silicon substrate, then treated with an RF capacitively-coupled glow discharge plasma in 50 mTorr He atmosphere, with -700V self-bias applied to the substrate As observed by FEG-SEM, before the treatment, the nanoparticles formed large aggregates over all the silicon, afterward, some particles were sputtered and the remaining ones fused with neighboring particles. Raman Spectroscopy of the sample before and post-treatment revealed a drastic difference in the observed spectra. The pristine carbon nanoparticle spectra displayed only a broad photoluminescent(PL) spectrum. After the treatment, a reduction of the PL spectrum was observed, showing the D and G band peaks at 1326 and 1527 cm^{-1}respectively, with G-band FWHM of 130 $cm^{-1}$and I(D)/I(G) of 0,65. We concluded that the PL decrease was due to the creation of larger sp^2clusters and sp^3defects on the hydrogenated carbon matrix, because of the non-equilibrium effects during ion bombardment, which can be explained by the knock-on subplantation model. The observed features of the Raman spectrum were strongly different from those obtained from samples thermally treated at temperatures ranging from 200°C to 500°C.

e-mail: rita.rangel@gmail.com

Although carbon steel is a widely used material, it is easily oxidized when exposed to the atmosphere. An interesting group of protective layers are the so-called smart coatings, which provide a viable solution to deal with the challenges of corrosion in a wide range of applications due to their promising properties to regenerate after suffering some damage, which is known as self-healing. Among these coatings are those containing cerium. In view of this, the present work aims to investigate the effectiveness of the dilution of cerium nitrate in TEOS (tetraethyl orthosilicate) for the deposition of protective organosilicon films against corrosion on carbon steel by the technique of Plasma Enhanced Chemical Vapor Deposition, PECVD. Plasma was generated by applying a DC voltage (400 V) in a vapor environment of cerium nitrate diluted in TEOS solution and argon. The variation of the total pressure of the gases in the properties of the layers was investigated. Scanning electron microscopy (SEM) was used to evaluate the surface microstructure of the layers. A dispersive energy analyzer coupled to the microscope was used to identify the chemical species present on the surface. Infrared spectroscopy (FTIR) was used to analyze the chemical composition and molecular structure of the layers. Electrochemical Impedance Spectroscopy (EIS) was applied to evaluate corrosion resistance. The thickness and deposition rate of the films were determined by profilometry, while the wettability was determined by the sessile drop method. The infrared spectra revealed groups of organic species and also bands referring to the asymmetric stretching of the nitrate ion, which comes from the dissociation of the $Ce(NO3)3$ salt.

Sulfate Radical SO4•— Activation by Plasma Electrolysis studied by Computational Chemical Dynamics

Andressa Mota-Lima[1]

[1]Escola Politécnica de Universidade de São Paulo (*Engenharia Química*)

e-mail: abmlima@gmail.com

In situ generation of either hydrated electrons (e_{aq}^-) or radicals such as sulfate ($SO_4^{\cdot -}$) and hydrogen (H·) have a central role for Advanced Oxidation Processes (AOPs) of enviromental pollutants like perfluorooctanoates (PFOAs) and perfluorooctanesulfonates (PFOS), being the plasma electrochemistry an electrified technology capable of producing all those three species in any water matrix. Making maximum use of the recently developed model for the chemical dynamics driven by the plasma-induced hydrated electrons (e_{aq}^-) beneath the electrified plasma-liquid interface (EPLI), this work elucidates the employment of plasma electrolysis to reduce $S_2O_8^{2-}$from an empirical theoretical perspective. This work proposes chemical reaction networks driven by the radical $SO4^{\cdot -}$and analyzes their respective chemical dynamics via computational experiments. In summary, this work identifies the core mehcanism of sulfate radical activation via plsama electrolysis in two water matrixes, namelly (a) acidified ultrapure water and (b) chloride-rich water. The results demonstrate that plasma electrolysis enables SO4·— local concentration as high as 350×10^{-6}mol L^{-1}, which can lead to the instantaneous mineralization (full oxidation) of up to 1.18 ppm of phenol, used here as a model pollutant. Besides identifing the core mechanism of sulfate radical activation by the plasma electrolysis, the results of this work offers valuable assistance in order to carry out bench experiments of PFOAs and PFOS oxidation.

Surface properties of Nb_2O_5/AZO thin films grown by HiPIMS at room temperature

Perovskite solar cells (PSCs) have shown remarkable progress in recent years with rapid increases in conversion efficiency, from reports of about 3% in 2006 to over 25% today [1]. Transparent and selective electrodes are crucial for PSCs performance. In particular, niobium pentoxide (Nb_2O_5) is a promising material to be used as electron selective layer due to its high stability [2]. Additionally, Nb_2O_5 is non-toxic and derives from readily inexpensive source materials. In this work, Nb_2O_5 and Nb_2O_5/AZO thin films were grown on glass at room temperature. A 1kHz High-power impulse magnetron sputtering (HiPIMS [3]) source at a power of -600 V on pulse and different duty-cycle was used. Optical reflection and transmittance were measured using a UV-Vis-NIR spectrometer (Lambda 750, Perkin Elmer) over the wavelengths from 190 nm to 2500 nm. All samples show average transmittances greater than 80% in the visible region. The refractive index at 500 nm of Nb_2O_5 and AZO thin films was around 2.4 and 1.9, respectively. Surface morphology was measured with atomic force microscopy (XE-100, Park Instruments) operating in air. All AFM images of the films were analyzed using scaling concepts. The RMS roughness remained around 10 nm for AZO (650 nm thick) and Nb_2O_5 (75 nm)/AZO (650 nm) The wettability behavior was measured using a Goniometer (DSA25E, Kruss). AZO and Nb_2O_5/AZO surface shows a contact angle lower than 75 and 50°, respectively.

e-mail: alinnsampaio@gmail.com

The growing microbial resistance to different antimicrobial agents has been a global concern and factors such as excessive and improper use of antibiotics have been pointed out [1]. Thus, the search for new effective treatment methods with a broad antimicrobial spectrum is urgent [2] and non-thermal plasmas have stood out for their antibacterial and antifungal effects [2;3]. This study aimed to evaluate the antimicrobial action of a home-made prototype of cold atmospheric plasma jets (CAPPJ) against pathogenic species. Suspension of Gram-positive bacteria ***Staphyloccocus aureus***and Gram-negative P*seudomonas aeruginosa*and *Candida albicans*fungus were standardized with sterile saline solution (10^6cell/mL). Inhibition tests were made on Brain Heart Infusion agar plate for bacteria and Sabouraud dextrose for fungus that were seeded with standardized suspensions followed by drying for 15 min. The antimicrobial effect of CAPPJ with helium (He) gas was evaluated at a power of 75 mW, distance of 2 cm and at times of 1, 2, 3 and 5 min. Control group was exposed to He gas only (no plasma). The tests were performed in triplicate at two different times. The inhibition zone’ s area was calculated using the Kruskal Wallis statistical test followed by the Dunn''s multiple comparison test. An increase in the zone of inhibition area was observed as the time of exposure to CAPPJ increased in all evaluated microorganisms. Control group did not show zone of inhibition. For ***S. aureus***and ***P. aeruginosa***bacteria, a statistically significant difference was observed between the area of inhibition after 3 min (2.74 mm^2, p=0.0008; 32.97 mm^2, p=0.0015) and 5 min (6.41 mm^2, p=0.0004; 40.68 mm^2, p=0.0008) compared to control. Differently, the zone of fungal inhibition was statistically different from control group after 2 min (2.74 mm^2, p=0.0354) and 5 min (7.58 mm^2, p=0.0001). These findings demonstrate the promising antimicrobial capability of the He CAPPJ for future biomedical applications.

Thermo-optical and mechanical properties of HastelloyX superalloy nitrided surfaces.

Regiane Gordia Drabeski[1], Rafael Fillus Chuproski[1], Isabel Borges da Rocha[1], Daniele Toniolo Dias[2], Anderson G. M. Pukasiewicz[2], Gelson Biscaia de Souza[1]

[1]Universidade Estadual de Ponta Grossa, [2]Federal University of Technology-Paraná

e-mail: regianedrabeski@gmail.com

The nickel-based Hastelloy X superalloy was nitrided by plasma imersion ion implatation for the first time in this study. The acceleration voltages were 8 kV and 10 kV, resulting in 360 ºC and 330 ºC, respectively. Crystal structure and surface mechanical properties were compared with the respective substrates, aged by the process heating. The modified layers retained up to 20% of N atoms in both conditions. The nitrogen diffusion in the matrix obeyed a complex and dynamic correlation with temperature due to the competitive nitrogen retention in interstices and precipitates. Raman spectroscopy allowed analyzing the formation of nitrides as Cr2O3, Fe2O3, Fe3O4, FeCo3 and TiN on the top surface (few nanometers). The structure at deeper regions, as inferred by X-ray diffraction, comprised the N-expanded austenite phase (the S-phase) as the main modification imposed by nitriding. The nitrogen inlet yielded strengthened cases, with hardness values reaching 8 GPa and elastic modulus 200 GPa (4 times and 40% higher than the substrates, the values were 3,8 GPa and 160 GPa, respectively). By photoacoustic spectroscopy, band gap values are in the range of the u-v energies for 8 and 10 kV treatments, respectively. These results are of intrinsic importance for the load bearing capacity and heating dissipation of the modified surfaces on the nickel superalloy.

Titanium protective, self-cleaning thin films depositedby plasma magnetron sputterring on the surface of solar panels installed on a floating solar plant

e-mail: emerson@elejor.com.br

Solar panels are currently a clean form of energy generation and are gradually replacing the energy matrix of countries. Centralized generation usually takes up large spaces that could be used for agricultural or reforestation activities. Therefore, their implementation in hydroelectric power plant lakes is an alternative. The exposure of these panels is conditioned by the accumulation of surface contaminants that can be of organic and/or inorganic origin. This new surface limits the passage of light, reducing the capacity for electricity generation. Periodic manual or mechanized cleaning methods are employed to remove the cemented dirt on the surface, however, this involves the use of qualified professionals, water resources that may not be available in many cases, cleaning chemicals, etc. With the aim of mitigating and maintaining the surface of the panels clean for longer, this research investigated materials and processes for the deposition of thin titanium films on the surface of glass sheets using the magnetron sputtering plasma technique. The films obtained were deposited on glass sheet surfaces with thicknesses varying linearly with the deposition time. After the heat treatment, the transmittance of the coatings with times up to 30 s was approximately 98%. From the wettability test, the hydrophilicity of the new surface was observed, with wetting angles below 15°, being considered self-cleaning.

e-mail: joao.icaro@unesp.br

Calcium-containing coatings, such as apatite, are important for bone integration of implants because the calcium release triggers a series of biological responses that favor a stable chemical bond. It is known that the direct deposition of apatite on titanium can lead to adhesion failures, but the effectiveness of adhesion can be improved by structural and morphological modification of the surface of the material. This study evaluated the influence of titanium oxide containing calcium as an intermediate layer. This layer was prepared by two different methods: sol-gel/dip coating and plasma-assisted oxidation (PEO), on which the apatite film was deposited via the sol-gel method associated with dip-coating. The intermediate films consisted of rutile and anatase TiO2, and CaTiO3. The apatite film was composed of two phases: hydroxyapatite (HAp) and β-tricalcium phosphate (β-TCP). Roughness analyzed by Atomic Force Microscopy (AFM) decreased when apatite was deposited on the intermediate films, while the wettability increased. Micrographs taken byScanning Electron Microscopy (SEM) showed that the modified surface exhibits cracks andsplits when prepared via sol-gel, while PEO processing produced a porous surface. Thethickness of apatite films deposited directly on Ti-c.p. (commercially pure titanium) was 1.5µm, but varied to 0.6 µm and 2.5 µm when deposited on CaTiO3 intermediate films obtainedvia sol-gel and modified by PEO, respectively. Both coatings reduced the corrosion rate, aswell as no significant changes were observed for bending stress and elasticity modulus. Inthe direct contact toxicity assay, pre-osteoblast viability (MC3T3, subclone 4) was lower onsurfaces modified via PEO, apatite, and CaTiO3 with apatite. On the other hand, the deposition of apatite films on PEO-modified Ti-c.p. significantly increased viability. The adhesion of pre-osteoblasts was higher on all samples compared to the control.

Treatment of commercial fabric with a Conical-Shaped Atmospheric Pressure Plasma Jet

Bruno Henrique da silva Leal[1], Felipe Vicente de Paula Kodaira[2], Konstantin Georgiev Kostov[3]

[1]Universidade Estadual Paulista (*Laboratório de Plasma e Aplicações/ Faculdade de Engenharia e Ciência de Guaratinguetá*) , [2]Universidade Estadual Paulista (*Laboratório de Plasma e Aplicações/ Departamento de Física da Faculdade de Engenharia e Ciência de Guaratinguetá*) , [3]Universidade Estadual Paulista (*DFI*)

e-mail: silva.leal@unesp.br

The textile industry is one of the largest and most developed industries in the world, requiring constant updates and modernizations in various processes [1]. One of the common and widespread practices in the industry is starching fabrics [2], which improves their resistance to friction and prevents unraveling of the textile structure. However, starch coating reduces the wettability of the textile fiber, making it difficult for subsequent finishing processes, such as painting. Typically, after the coating process, fabrics undergo further treatment to improve their wettability, aiding in the finishing processes of the textile production line [3]. The study aimed to investigate the effect of atmospheric plasma generated by a conical-shaped atmospheric pressure plasma jet. Cotton (CO) and polyester (PES), the two most commonly used textile materials, were used to create fibers, with both fabrics constructed using the Oxford method and distinct compositions. The first fabric was made entirely of cotton, and the second was a blend of 33% cotton and 67% polyester. To analyze the physical and chemical changes caused by the treatment, several surface characterization methods were used, including the vertical wicking test, Fourier-transform infrared spectroscopy (ATR-FTIR) with attenuated total reflection, scanning electron microscopy (SEM), and X-ray photoelectron spectroscopy (XPS).

Zinc Oxide Film on Glass Substrates by Means of Plasma Immersion Ion Implantation and Deposition

Eduardo Cezar Barbosa de Barros Aragão[1], Maxson Souza Vireira[2]

[1]Universidade Federal dos Vales do Jequitinhonha E Mucuri (*IECT*) , [2]Instituto Federal de Educação, Ciência e Tecnologia da Bahia

e-mail: cezaragao@yahoo.com.br

Zinc Oxide, a semiconductor material, presents many interesting characteristics to electronics industry[1-6]. This paper shows a process for coating glass with ZnO by Plasma Immersion Ion Implantation and Deposition (PIII&D). The process consists of zinc deposition on the glass surface and post-oxidation to form ZnO. In the process, small pieces of metallic zinc filling the top of a crucible are immersed in an argon and oxygen plasma; the crucible is positively biased and draw electrons from a termionic electron emitter, which is composed of a tantalum foil covered with (Ba, Sr, Ca) O. The low work function of this oxide cathode is essential to supply enough amount of electrons to heat the crucible to temperatures ranging from 400 to 450 o C, leading to vaporization of the zinc. The zinc vapor is partially ionized by of collisions with argon ions and electrons from the plasma. High negative and repetitive voltage pulses (10kV/20μs/250Hz) applied to a sample holder containing the glass slices causes the implantation of zinc ions into the glass surface; between pulses zinc is deposited onto glass substrate. After treatment, the samples were characterized by X-ray diffraction (XRD) in the mode of thin films, atomic force microscopy (AFM), scanning electron microscopy (SEM), Optical Profilometry and Transmittance. The XRD analysis showed the presence of crystalline ZnO after annealing. The AFM analysis as deposited showed the formation of microstructures. Topography viewed by SEM and Optical Profilometry showed the formation of structures with nanostructures after annealing. The optical transmittance reached 51.8% of transmittance in visible wavelength range. The PIII&D allowed to growing nanostructures of ZnO on glass without the need of a buffer layer.

P-Polysaccharide-based Materials

Expanding the property space of polysaccharides through peptide conjugation

Rupert Kargl[1]

[1]Graz University of Technology (*Institute for Chemistry and Technology of Biobased Systems*)

e-mail: rupert.kargl@tugraz.at

Polysaccharides combined with peptides are ubiquitously found in biology and fulfil destinctive structural and signalling functions. The best known examples include peptido- and proteoglycans, both of which have very different (supra-)molecular forms and biological roles. Imitating those structures by semi-synthetically combining polysaccharides with short peptides can potentially contribute to medical therapies including drug delivery or regenerative medicine. Drug delivery requires the binding and controlled release of drugs by splitting covalent bonds or non-covalent complexes, whereas regenerative medicine often makes use of cross-linkable but degradable gels to embed cells or tissue. Derivatizing polysaccharides with peptides in a very defined way requires special chemical tools, not all of which are yet availble. Combining biological methods with chemical ones is one of the options to create new conjugates. Upon attachment of peptides to polysaccharides, their structure and properties change significantly, requireing sophisticated analytical methods to study these. This presentation first gives an overview on the motivation and the state-of-the-art of studying polysaccharide peptide conjugates. It then communicates selected examples of where and how conjugates have been designed, analyzed and applied and concludes with suggestions for further studies of the topic.

Exploiting the potential of polysaccharide in the development of advanced bioinks for 3D bioprinting applications

Carmen S. R. Freire[1]

[1]CICECO - Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, Portugal

e-mail: cfreire@ua.pt

3D bioprinting is a technique with undeniable potential in the biomedical field, resulting in the fabrication of living structure analogs that may be used in tissue engineering, new drugs testing and diseases research. The cell-laden materials used to create these 3D structures are called "bioinks". The precise layer-by-layer deposition of the bioinks, in a computer-controlled manner, originates complex 3D constructs with tailored size and structure, loaded with living cells that could proliferate in the matrix. Understandably, the characteristics of the bioinks majorly influence the success of the 3D bioprinting procedure, and the performance of the resulting constructs. A perfect bioink should possess adequate rheological, chemical, mechanical, and biological features to originate stable structures where the living cells can thrive. Given so, the development of bioinks with improved properties is a very relevant and active research topic in this area. Particularly, hydrogel bioinks derived from biopolymers, especially polysaccharides, have been widely explored because of their low cytotoxicity, high hydrophilicity, and closely mimic the native extracellular matrix. Furthermore, the tunability and facile crosslinking of polysaccharides, together with their recognized abundance, place polysaccharides hydrogels in the spotlight regarding the design of novel bioinks [1].

In this talk, innovative studies about polysaccharide-based hydrogel bioinks for 3D bioprinting of diverse cell lines, will be presented and discussed, with emphasis on their compositions, rheological properties, printability, biological performance and role of polysaccharides in the bioink formulations.

Exploiting the properties of chitosans innanostructured films

Osvaldo Novais de Oliveira Junior[1]

[1]Universidade de São Paulo

e-mail: chu@ifsc.usp.br

Chitosans are now used in two main types of nanostructured films, namely on layer-by-layer (LbL) films as matrix for sensors and biosensors and on Langmuir monolayers that mimic cell membranes. In this lecture, chitosan-containing LbL films will discussed which are used in preserving the activity of biomolecules in biosensors and as sensing materials in electronic tongues (e-tongues). For example, an e-tongue was built with LbL films made of chitosan, chondroitin sulfate, sericin and gold nanoparticles to detect S.aureus in milk, which is used in the diagnosis of mastitis. A precise diagnosis was achieved by treating the impedance data obtained with the e-tongue a machine learning method. As for the chitosan incorporation into Langmuir monolayers, a set of results will be employed to correlate the activity of chitosans as bactericide agent and their interaction with cell membrane models. Of particular relevance will be the discussion of tailored chitosans synthesized in order to be soluble in water, which permits a more realistic comparison of biological effects.

FUTURE POLYSACCHARIDES RESEARCH AND DEVELOPMENT TRENDS PRESENTED IN THE EPNOE ROADMAP 2040

Karin Stana Stana Kleinschek[1], Pedro Fardim[2]

[1]University of Technology Graz（*Institute for Chemistry and Technology of Biobased Systems*）,
[2]KU Leuven（*Department of Chemical Engineering*）

e-mail: karin.stanakleinschek@tugraz.at

EPNOE was established in May 2005 as a European Polysaccharides Network of Excellence Network with funding from the European Commission (EC) and was registered as a non-profit association and continued its activities after the end of EC funding in October 2009. EPNOE prepared and presented in the spring 2023 the EPNOE Roadmap 2040 (https://www.epnoe.eu/discover/research-roadmap/), which has strong and synergistic links to EU strategies and objectives, including the EU Bioeconomy strategy, EU Green Deal, EU Missions, Horizon Europe Clusters, and EU Industrial Strategy. The EPNOE Roadmap 2040 strategic areas are prepared considering the broadness of the topic and the gaps and uncertainties of available literature. The roadmap is based on the knowledge and skills of experienced researchers, scientists and academics. Each topic discusses the current challenges, expected achievements and developments in the coming 20 years, and the required research activities needed for the understanding of the most important scientific and societal questions to be answered. The main goal of this Roadmap is to arrive at solutions for a sustainable use of biomass resources while keeping biodiversity. The strategic choice of research activities in polysaccharides as a part of a very diverse biomass is very important and essential in achieving a sustainable development of our societies.

MATERIALS RECENTLY DEVELOPED AT THE GMPC- UEM / LIMAV-UFPI BASED ON POLYSACCHARIDES AND THEIR POTENTIAL FOR TECHNOLOGICAL USES

Edvani Curti Muniz[1,2,3]

[3]Universidade Tecnológica Federal do Paraná (*PPGCEM*)

e-mail: curtimuniz@gmail.com

This lecture will present recent results (last 10 years) from our research groups at GMPC/UEM (Polymeric Composite Materials Group, at UEM-Maringa-Brazil); and at LIMAV/UFPI (Advanced Materials Interdisciplinary Laboratory, at UFPI-Teresina-Brazil), in developing materials based on polysaccharides with potential for technological applications in the following fields: i) environmental (adsorption of contaminants using hydrogels); ii) agriculture (soil conditioners for humidity maintenance and carriers for releasing of plant nutrients); and iii) biomedical (controlled release of drug bactericidal actio substrates for cell growth; materials with virucidal action to combat the SARS-Cov 2 virus, related to the recent corona virus pandemic). The polysaccharidic-based materials are mainly prepared by means of three-dimensional matrices (hydrogels) polyelectrolyte complexation between anionic/cationic polymers of chemically modified (or not) polysaccharides in presence (or absence) of ionic liquid and by means of the electrospinning technique [1,2]. Several methodologies will be shown and discussed, targeting to obtain matrices of different geometries (cylindrical, spherical, irregular particles, thin films, nanofibers, etc.) of different sizes (macro, micro and nanometric scales). In the last part of the talk, information of the INCT-Polysaccharides, recently approved by CNPq-MCTI-Brazil, evolving research groups from 15 Brazilian universities, and at this moment in implementation, will be given.

Mesoporous polysaccharide-based carriers as future sustainable materials for pharmaceutical applications

Pedro Fardim[1], Fan Xie[2], Guy Van den Mooter[2]

[1]Katholieke Universiteit Leuven (*Chemical Engineering*) , [2]Katholieke Universiteit Leuven (*Pharmaceutical Sciences*)

e-mail: pedro.fardim@kuleuven.be

Polysaccharides are abundant renewable materials with outstanding structural diversity and functionality. Polysaccharides have been extensively utilized in pharmaceutical applications such as thickeners, suspending agents, emulsifiers, stabilizers, gel forming agents, binders, disintegrating agents, matrix formers, release retardants, film formers, coating materials and mucoadhesive agents. They have been also exploited as excipient in different pharmaceutical dosage forms for example microparticles, suspensions, emulsions, gels, tablets, capsules, beads, microparticles, nanoparticles, liposomes, transdermal formulations, to name a few. In this talk we will present and discuss the design and fabrication of stimuli-responsive porous polysaccharide materials with dual function: drug amorphization and stimuli-responsive controlled delivery. Cellulose microspheres fabricated using water-based solvents and antisolvents were post-functionalized via oxidation or via oxidation and addition of amino acids. Hydrophobic drugs were encapsulated in mesopores of the microspheres resulting in amorphous solid dispersions. Drug-loaded microspheres showed pH stimuli responsive delivery at different pHs, simulating gastrointestinal conditions. The pH-responsive oxidized cellulose beads with good biocompatibility, low cost, and adjustable release rate have shown great potential in the field of controlled drug release. This is the first study that reports on exploiting soluble, porous, dialdehyde cellulose beads and novel pH responsive amino cellulose beads, showing excellent potential as a carrier for improving the rate and extent of dissolution of poorly soluble drugs and maintaining supersaturation.

Nanostructured biomass for multifunctional materials

Luiz Henrique Capparelli Mattoso[1], Caio Gomide Otoni[2]

[1]EMBRAPA Instrumentação (*LNNA*) , [2]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais*)

e-mail: luiz.mattoso@embrapa.br

A wide range of biomass-derived polysaccharides has been widely explored by the scientific community lately in response to the run towards eco-efficient materials delivering advanced functionalities. Our group has been focusing on cellulose, chitin, pectin, starch, alginic acid and their derivatives, to mention a few, either as colloidal or molecular building blocks for (nano)composite films, coatings, mats, and parts with suitable properties for a range of applications, such as electronic devices, biocidal surfaces, delivery platforms, biodegradable packaging, edible films, and cell growth scaffolds. This talk will cover the most relevant aspects of the compositions, assemblies, and processing methods of such materials.

e-mail: lucas_santos@usp.br

3D printing is enables to the production of custom bone scaffolds and the use of starch (a natural polymer biocompatible and biodegradable) [1] incorporated by hydroxyapatite nanoparticles (HA) replaced by strontium ions is one potential biomaterial to induce bone formation and to reduce bone reabsorption [2]. In this context, this work evaluated the bioactivity of 3D printed produced bone scaffolds based on potato starch gels added with HA nanoparticles replaced by different molar percentages of Sr2+ ions (0,30,50,70, and 100%, HA_0, HA_30, HA_50, HA_70, HA_100) for a possible application in guided bone regeneration. The formulations (inks) were based on potato starchy hydrogels (10% w/w, d.b.) added of HA (5% w/w starch, d.b.). The scaffolds were printed using a 3D printing extrusion (BioedPrinterV4, Brazil). The printed scaffolds were characterized concerning swelling, biodegradability, cytotoxicity by MTT assay using MC3T3-E1 pre-osteoblasts cells, and the alizarin red assay to evaluate the ability of the membranes to induce mineralization. The HAp_100 showed the highest biodegradability value (70% in 14 days). The scaffolds showed significantly swelling in 2 h in medium (~60%); after this period, the swelling was not noticed. All scaffolds showed no cell toxicity. HAp_100 stood out positively in cell proliferation. Furthermore, scaffolds containing HAp had higher mineralization than ones without in both time intervals, and this effect was more evident with an increasing degree of Sr2+ substitution in the nanoparticles. It is evident that the incorporation of HAp and various levels of Sr2+ substitution has improved the properties of scaffolds for use in bone regeneration. Finally, 3D printing technology and starch holds significant promise for this application.

scampana@iqsc.usp.br

Direct ink writing (DIW) 3D printing was employed to produce asymmetric membranes based on N-(2-hydroxy)-propyl-3-trimethylammonium chitosan chloride (QCat), beta-chitin whiskers and genipin as crosslinking agent with potential biomedical applications. Chitosan was produced from beta-chitin by using ultrasound-assisted deacetylation (USAD) [1] and acidolysis of beta-chitin was carried out to produce whiskers. The QCat derivative was synthed through the reaction of chitosan with glycidyltrimethylammonium chloride (GTMAC) in slightly acidic medium. The ink for the DIW 3D printing was produced through the solubilization of QCat in beta-chitin whiskers aqueous suspension, followed by the addition of genipin. The membranes were printed with two layers with different geometries. The rheological behavior of the ink used for DIW 3D printing was evaluated through shear thinning, viscoelasticity and thixotropy assays for samples with and without addition of genipin. QCat showed average degree of substitution ((DS) ¯) ~ 30%, which provided water solubility in a wide pH range and antimicrobial activity against E. Coli and S. aureus, as evidenced by MIC and MBC assays. The ink for DIW 3D printing showed pseudoplasticity, thixotropy, solid-like behavior under low oscillatory strain and liquid-like behavior under high oscillatory strain, which are ideal characteristics for DIW 3D printing. The asymmetric membranes showed contact angle of 59.4° ± 7.6° for the outer layer, swelling capacity inPBS buffer ~ 35% and total degradation after 7 days of in vitro incubation with lysozyme.The asymmetric membranes showed contact inhibition against E. coli and S. aureus in thedisk diffusion test, a notable feature considering biomedical applications.

AIR AND OXYGEN PLASMA PEN TREATMENT ON THE GELATINATION OF CORN STARCH

Renata Antoun Simão[1]

[1]Universidade Federal do Rio de Janeiro (*Programa de engenharia metalurgica e de Materiais - PEMM*)

e-mail: renata@metalmat.ufrj.br

In this work, corn starch was modified by atmospheric pressure plasma jet (APPJ) using air and oxygen gases and the properties of starch granules and gelatinized films produced from them was evaluated. Two different routes were chosen: starch granules were modified by APPJ either using compressed air (air treatment) or by using ultra pure 99.99% pressurized oxygen (O2 treatment). Contact angle and FTIR for films produced from both starches were evaluated after two different treatment times: 30 minutes and 40 minutes of treatment. The pH of a 7.5% starch slurry in water was measured before and after treatment and it was observed that air plasma led to an increase in medium acidity while oxygen plasma led to its alkalinization. After gelatinization, air APPJ treatment led to a more hydrophobic film while O2 APPJ to more hydrophilic films. FTIR was performed in the films and no clear chemical modification was detected that could explain this behavior. XRD, DSC and viscosity measurements gave us a clue of the observed phenomena and will be discussed.are being measured in order to better understand these modifications. Therefore, APPJ is a clean technology for starch modification, changing pH showing great potential for applications both for food and non-food applications.

ALGINATE SPRAYS LOADED WITH SAPONINS FROM THE SAQTA ROOT (Colignonia parviflora subsp. Biumbellata) APPLIED FOR THE DESORPTION OF IMPREGNATED OIL IN ROCKS

ANA CECILIA VALDERRAMA NEGRÓN[1], Miguel Angel Veliz Hinostroza[2], Éder Tadeu Gomes Cavalheiro[3], TIAGO VENÂNCIO[4], JUAN LOPEZ VALENTÍN[5], JUAN DÁVALOS PRADO[5], OLIVIO NINO CASTRO MANDUJANO[6]

e-mail: ana.valderrama.n@uni.edu.pe

The exploitation and transportation of oil by private companies or industries, where spillage accidents occur frequently, generate environmental problems that cause destructive damage to the ecosystem of the ocean and the coast. This motivates states to generate new methods for oil removal.

This work is based on the method of enhanced oil recovery from mixtures of polymers and surfactants, being alginate and Saqta root saponins substances of interest for being eco-friendly.

The experimental phase begins with the extraction of the saponins by means of hydroalcoholic extracts from the Saqta root. This crude extract of saponins will be characterized by the instrumental techniques of FTIR, 1H-NMR and LC-MS.

Commercial alginate has been characterized by the instrumental techniques of FTIR, 1H-NMR, capillary viscometry, and TGA.

For the desorption tests, stones of similar have been collected in a coast area not contaminated by oil, in Lima-Peru. The alginate sprays have been prepared through an experiment design with three variables (%alginate, %surfactant and %plasticizer), obtaining formulations with synthetic surfactant (Tween 80) including glycerol and formulations with natural surfactant (saqta saponins) including xanthan gum. Spraying was applied to the sampled stones without oil together with a $CaCl_2$ crosslinker.

The formation of the film on the stone and its characteristics will be observed after every days. The sampled stones are submerged in crude oil for a few minutes and then allowed to drain into the environment for a day (Batch 1) and for a week (Batch 2). The sprays selected from the design of experiments were applied to each batch. The films formed with and without crude oil are removed from the stone and characterized by the instrumental techniques of FTIR, TGA and SEM. A quantitative analysis of total hydrocarbons will be carried out in the films formed to measure their crude oil removal capacity.

Carboxymethylcellulose production from sugarcane bagasse: a new approach in biorefinery concept

e-mail: camila.florencio@gmail.com

The production of carboxymethylcellulose from different raw materials has been carried out frequently, but obtaining it from agro-industrial residues is still little explored in terms of aspects such as performance, cost-effectiveness and sustainability. Here, sugarcane bagasse was used as raw material for the synthesis of carboxymethylcellulose (CMCb). The natural polymer CMCb was characterized and applied in a matrix for the encapsulation of the Trichoderma harzianum strain with the objective of application as a biocontrol agent. To complement the results, an estimate was made of the production cost of CMC obtained from sugarcane bagasse considering a CMCb plant attached to an established first generation ethanol biorefinery. For this, sequential treatments were initially used for the removal of hemicellulose and lignin and isolation of cellulose for the synthesis of CMCb. The conversion of cellulose into CMCb was carried out through the application of NaOH and monochloroacetic acid (MCA). The characterizations showed the chemical modifications of the materials until obtaining a CMCb with a degree of substitution of 0.44, purity of 71.3% and crystallinity of 32%. The samples were comparatively studied by FTIR, TGA and XRD. The growth and viability of free spores were compared with encapsulated fungus and the results were positive showing that the polymeric matrix allowed the growth of the encapsulated fungus and maintained its viability after a period of 5 months of storage. The minimum value of the selling price of the product calculated for the CMCb synthesis process was 16.8 US$/kg of product, this value is above the commercial carboxymethylcellulose. However, these data are important to provide as an initial guideline for the economic performance of CMC production from an agro-industrial residue and show the importance of using technical-economic tools to support decision-making in obtaining materials from waste in future biorefineries. Carrageenan beads: exploring drug delivery potential

Érica Mendes dos Santos[1,2], PRISCILA G MAZZOLA[1], Pedro Fardim[2]

[1]Universidade Estadual de Campinas (*Faculdade de Ciências Farmacêuticas*) , [2]Katholieke Universiteit Leuven (*Department of Chemical Engineering*)

e-mail: e229232@dac.unicamp.br

Polysaccharides are increasingly being used for drug delivery, and seaweeds have become a prominent source of these compounds, including carrageenan, alginate, and agar. Carrageenan (CRG), a natural sulfated polysaccharide, has thickening and gelling properties and is used in various industries. Moreover, it exhibits several biological properties, such as antibacterial and antiviral [1]. Thus, this study aimed to develop CRG beads loaded with neomycin. For bead production, a 3% CRG solution was dripped into a 4.5% KCl + 4.5% CaCl2 anti-solvent solution and stirred for 30 min. After washing, the beads were immersed in a 20 mg/mL neomycin solution for 24h. Encapsulation efficiency was determined by measuring the absorbance of the solution using a spectrophotometer. Additionally, mass uniformity was evaluated by weighing beads loaded with neomycin and without, incrementing from 5 to 50 beads, and analyzed through linear correlation between the number of beads and the weight [2]. Results showed an encapsulation efficiency of 20%, which is average for this type of bead. Both loaded and placebo beads demonstrated high mass uniformity, with a correlation of 0.999 for loaded beads and 1 for placebo. Thus, CRG beads exhibit adequate encapsulation efficiency and high mass uniformity, making this material suitable for various drug delivery applications.

Cellulose-based Materials: Important Player in the Circular Bioeconomy

Elisabete Frollini[1]

[1]University of São Paulo (*Sao Carlos Institute of Chemistry*)

e-mail: elisabete@iqsc.usp.br

Cellulose-based materials can play a critical role in the circular bioeconomy thriving. Forest biomass is a critical source of cellulose. However, others could be introduced in the specialized market, for example, lignocellulosic biomass, such as sisal, whose fibers have a high cellulose content. Also, the high cellulose content gives such fibers excellent mechanical properties, and, therefore, sisal is considered one of the top plant fibers for reinforcing polymeric matrix composites. Cellulose derivatization, as esterification, has been widely studied and reported in the literature, but there is still room for further exploration. Using cellulose as a macromonomer can lead to promising avenues for future research. Specifically, microcrystalline cellulose is a compelling synthesis option due to its relatively low average molar mass. In the context of those above, there has been an effort from our side to explore the esterification of sisal cellulose, aiming, for instance, to use the products in producing electrospun mats and forming functionalized films, for example, with magnetic nanoparticles. Numerous lignocellulosic fibers have been utilized to reinforce various synthesized bio-based polymeric matrices, emphasizing the application of sisal as short fibers or blankets. Biobased polyurethanes have been synthesized using microcrystalline cellulose as a polyol through multiple processes. The syntheses have formed molded composites reinforced by plant fibers, and films (with or without additives)and using different sources of isocyanate groups. Extensive characterization of all the mentioned materials has yielded promising results. All mentioned studies on cellulose-basedmaterials are in progress, always within the perspective of contributing to advancing thecircular bioeconomy. Studies on cellulose-based materials for application in the sorption ofmetals from water are currently in their early stages.

Densification of starch compound for direct dosing in thermoplastic starch extrusion process

Kelly Lucas Lizano[1], Antonio Aprigio da Silva Curvelo[2], Antonio José Felix Carvalho[1]

[1]Escola de engenharia de São Carlos – Universidade de São Paulo, [2]Instituto de Química deSão Carlos – Universidade de São Paulo

e-mail: klucasl@usp.br

Thermoplastic starch (TPS) is a promising biodegradable material. With the increasing development of TPS materials at an industrial level and from a technological point of view, there is a need to focus on improving the industrial processing system to make the most of its potential. A common previous mixture of starch and a plasticizer is prepared to obtain TPS which is called ***pre-mixture*** (PM). However, focus on the fine particulates of the starchy inputs, the use of PM presents a significant challenge due to its powder form which hinders the fluidity in hoppers. That approach is still an issue that requires investigation. In this work, densified compounds (DC) of starch and glycerol were produced to be directly used in the TPS extrusion process, as a fluidized alternative. Thus, different types of DC such as tablets, agglomerates and pellets were obtained. They were produced by direct dry compaction, wet agglomeration and agglomeration with a binder (gelatinized starch paste), respectively. The DC obtained were submitted to the extrusion process to obtain TPS. The DC were evaluated by dosing in a conventional extrusion hopper and characterized in terms of particle size distribution, structural analysis by SEM and thermal analysis by TGA. The TPS films, produced using both PM and DC, were also characterized through tensile tests, DRX and thermal analysis. The qualitative evaluation of tablets DC type aimed only to guarantee its formation and stability. The shape and conformation of the agglomerates were found to be dependent on the glycerol content and moisture level. Gelatinized starch proved to be effective to allow the formation of pellets. The use of densified starch feedstock resolved feeding issues in the extruder hopper. A complete breakdown of the starch granules was achieved when DC were used after extrusion. Mechanical properties showed inferior performance when compared with TPS samples using PM inputs.

e-mail: arthurgabriel98@gmail.com

Hybrid materials that combine polymeric matrices with inorganic nanoparticles have widely studied due to their potential applications in various fields. These materials offer a unique combination of physicochemical and biological properties, allowing for the creation of materials with different characteristics. Among the polysaccharides, chitosan is a naturaland cationic polymer derived from chitin, with an excellent biocompatibility, non-toxicity, and biodegradability properties, making it a useful material for forming films. The modification of the surface of nanoparticles plays a prominent role since this property can affect the interaction of the material with biomolecules, cells, and microorganisms. For example, conventional TiO_2 nanoparticles act as semiconductors, but when their surface is functionalized with peroxide groups (TiO_2-OPM), they begin to interact with visible radiation and produce reactive oxygen species (ROS), leading to superior antimicrobial activity. In this work chitosan films modified with TiO_2-OPM and TiO_2-red were synthesized by casting, using water as solvent. The purpose was to study the influence of surface peroxo groups on the characteristics of the material by comparing the two versions of nanoparticles. TiO_2 nanoparticles were synthesized using the oxidant peroxo method (OPM), TiO_2-red was produced by heat treating TiO_2 -OPM. The materials were submitted to optical, spectroscopic, mechanical, thermal, and structural characterizations and an optimization of loading conditions and release tests for dyes was carried out. Since the nanomaterials were distributed in the chitosan three-dimensional network, their concentration and structure influenced the thermal and mechanical properties of the films.

Fatty Acid Cellulose Esters (FACEs): Structure- properties relationship elucidation according to both fatty chain length and substitution degree – Toward high value-added applications

Nicolas Joly[1], Patrick Martin[1]

[1]Univ. Artois

e-mail: nicolas.joly@univ-artois.fr

A lot of studies on cellulose derivatives, including ours,[1] are dedicated to the determination of mechanical and/or thermal and/or structural properties of Fatty Acid Cellulose Esters (FACEs),[2] which is a great deal if we consider the investigations on the potential applications of such bio-based materials. Substitution degree (DS) and fatty chain length are the main parameters able to directly influence properties of FACE-type materials.[3] Interested in thermoplastic and hydrophobic FACE materials, the present study sums up almost 20 years of our research work, dealing with the influence of substitution degrees and fatty chain length on structure and properties of partially- and fully-substituted FACEs. A series of fatty acid cellulose esters (FACEs) with both various degrees of substitution (from DS=1.7 to 3) and side chain length were obtained by grafting aliphatic acid chlorides (from C10 to C16) onto cellulose backbone, in a homogeneous LiCl/DMAc medium. These materials were characterized by FTIR and ^{1}H NMR spectroscopies, as well as WAXS, DSC and mechanical analyses. Whatever the alkyl chains length and the DS, all samples displayed a layered structure. The alkyl chains were able to crystallize as soon as they are long enough. As the DS decreased, the plasticizing effect of the alkyl chains was less pronounced and their ability to crystallize was improved. Regarding the mechanical behaviour and chemical resistance, similar results were observed whatever the DS is. Some high added-value applications are mentioned, as materials or additives for biopolymers.

Acknowledgments: Authors thank Artois University, especially BQR, for financial support.

e-mail: pedrosponchiado@usp.br

One eco-friendly technology that is gaining attention is dry heating treatment (DHT), which has the potential to modify both the size and charge of starch molecules [1]. This research explores the use of DHT-modified potato starch, produced at varying levels (130°C for 1, 2,and 4 hours, called DHT_1h, DHT_2h, and DHT_4h), to create biodegradable films using the casting technique, along with glycerol as a plasticizer and water as a solvent. The films were analyzed for their mechanical, thermal, biodegradability, wettability, morphology, and crystallinity properties. The modified membranes exhibited a more uniform morphology compared to those produced with non-modified starch. The films based on DHT-modified potato starch displayed higher tensile strength (Native: 5 MPa and DHT_2h: 25 MPa), Young's modulus (Native: 10 MPa and DHT_2h: 1000 MPa), thermal stability (Tg of Native: 50 oC MPa and Tg of DHT_2h: 59 oC), and relative crystallinity (Native: 12% and DHT_2h: 23%), while the elongation at break was lower (Native: 20% MPa and DHT_2h: 5%) than that of the non-modified starch. Moreover, there was one reduction of biodegradability rate (~ 10%) and hydrophilicity (~ 20%) of the films with an increase in the dry heating treatment time, which can be interesting from a commercial standpoint. In summary, DHT-modified starch represents a promising alternative for the production of packaging materials.

FINE-TUNING CELLULOSE NANOFIBRILS FOR ENHANCED PACKING PERFORMANCE VIA ENZYME-ASSISTED DEFIBRILLATION

Bruno Las-Casas Chaves[1], Valdeir Arantes[1]

[1]Escola de Engenharia de Lorena - EEL/USP (*Laboratory of Applied Bionanotechnology, Department of Biotechnology*)

e-mail: brunochaves@usp.br

Cellulose nanofibrils (CNFs) have emerged as a potential alternative to synthetic polymers in packaging applications owing to their oxygen and grease barrier performance and mechanical properties. The performance of CNF films is highly reliant on the intrinsic characteristics of fibers, including crystallinity, aspect ratio, degree of polymerization, and surface area. These characteristics may be significantly altered during the CNF isolation process, and it is important to note some properties may be enhanced others may be compromised. Therefore, understanding the changes in these characteristics during CNF isolation is crucial for tailoring CNF film properties to achieve optimal packaging performance. This study utilized endoglucanase-assisted mechanical ultra-refining to isolate CNFs, and systematically investigated the variations in their intrinsic characteristics and their impact on CNF films as functions of the degree of defibrillation, enzyme loading, and reaction time using statistical design of experiments. The isolation process was optimized to isolate CNFs with desirable characteristics for packaging and minimize tradeoffs. CNF films prepared from CNFs isolated under the optimized scenarios exhibited high thermal stability (approximately 300 °C), high tensile strength (104-113 MPa), high oil resistance (kit n°12),and low oxygen transmission rate (1.00-3.17 cc·m^{-2}.day^{-1}). Therefore, endoglucanase pretreatment allowed the isolation of CNFs with lower energy consumption, resulting in films with higher transmittance, higher barrier performance, and lower surface wettabilitythan the control samples without enzymatic pretreatment and other unmodified neat CNFfilms reported in the literature. Moreover, the mechanical and thermal performance of theCNF films was not significantly compromised.

Influence of acid treatment on the properties of beta-chitin nanoparticles

Filipe Biagioni Habitzreuter[1], Sérgio Paulo Campana-Filho[2]

e-mail: filipeh@usp.br

Chitin nanoparticles, often called whiskers, are usually obtained through acidolysis. This work describes the production of beta-chitin whiskers by acidolysis with HCl, $H_2SO_4$and H3PO4 along with their structural and physicochemical properties. The starting beta-chitin had very high average degree of acetylation GA≈96% as determined by ^{13}C NMR spectroscopy, as well as high viscosity average molecular weight Mv≈413,000 g/mol. Characterization of whiskers revealed that *N*-deacetylation did not occur and that acidolysis predominantly promoted the breakdown of glycosidic bonds, leading to Mv≈10,000 g/mol. The morphology of beta-chitin whiskers was characterized by TEM and AFM. The images indicate that whiskers produced by HCl and H_2SO_4resemble needles, while those produced by with H_3PO_4exhibited a spherical shape and reduced size. Structural differences were also observed by NMR and FTIR spectroscopy, especially in the case of the H_3PO_4sample. It was found that there was a conversion of beta-chitin to alpha-chitin in this case, evidenced by the presence of characteristic resonance peaks, i.e. the splitting of signals referring to C3-C5 (≈ 75 ppm) and C6 (≈ 65 ppm) and splitting of the bands of amide I (≈ 1610 cm-1) in the FTIR spectrum and also higher indexes of short-range crystallinity (≈ 89%) calculated by ^{13}C NMR. Different behaviours were also observed in the thermal degradation profiles, in which beta-chitin whiskers produced with H_3PO_4showedhigher degradation temperatures (≈ 300 ºC), whereas the other samples had peak degradation at ≈ 250ºC. None spectroscopic evidence of the presence of sulfate and phosphate groups on the beta-chitin whisker surfaces was observed. These results indicatethat the nature of the acid used for acidolysis plays an important role on the properties of beta-chitin nanoparticles, especially leading to the conversion of beta-chitin into alpha-chitinin the case of using H_3PO_4.

e-mail: scampana@iqsc.usp.br

An innovative multifunctional material has been developed and characterized based on poly(lactic acid) (PLA) nonwoven produced by solution blow spinning and electrospinning, and modified by depositing beta-chitin whiskers on a single face and spraying silver nanoparticles (AgNPs) on it. Regardless of the spinning technique, bead-free PLA hydrophobic nonwovens were produced, while carrying out the post-modification steps on one of the membrane faces turned it hydrophilic due to the presence of numerous hydroxyl groups in the beta-chitin chains. Additionally, spraying AgNPs on such a surface resulted in antibacterial activity against S. aureus and E. coli. Moreover, the PLA-based nonwovens modified by beta-chitin whiskers and silver nanoparticles exhibited high surface area and porosity (>80%), biocompatibility towards human dermal fibroblast (HDFn, stability in aqueous medium even in the presence of lysozyme, high swelling capacity in acetate and PBS buffers and improved mechanical properties. Results show that such PLA-based materials combine several advantageous features and hold great promise as a potential multifunctional wound dressings.

Production and characterization of novel mixed-mode beads for protein adsorption and purification

Pedro Fardim[1]

[1]Katholieke Universiteit Leuven (*Chemical Engineering*)

e-mail: pedro.fardim@kuleuven.be

Research in protein adsorption is of great interest because it is the key step of downstream purification in pharmaceutical and food industry. Different low-cost biopolymers have been examined to obtain beads with high adsorption capacity. These bio-based materials have drawn the attention of the scientific community in this application for their outstanding biological characteristics and wide availability. Hence, a study for producing different bio-based beads for protein adsorption is justified. In this work, we present a method to produce new mixed-mode beads and examine the feasibility of their application in proteins separation and purification. The composite beads were produced by combining different polysaccharides i.e. pullulan, agar and guar gum with alginate. These novel beads were first characterized by Fourier transform infrared spectroscopy (FTIR) and then their swelling ratio was calculated and analysed. Subsequently, adsorption experiments were performed to clarify whether the materials are suitable for protein adsorption. The protein adsorption was made using bovine serum albumin (BSA) (a model protein) in solution. It was found that all the beads can perform protein adsorption in the different buffer solutions. Therefore, a selection among the different composite beads considering the best performance was made. The one containing the same composition of alginate and pullulan and the one containing alginate were selected. The adsorption of the beads selected was studied in detail and the composite beads were further characterized. The adsorption mechanism is discussed, and the characterization was conducted using scanning electron microscopy (SEM) analysis, nitrogen physisorption and the quantification of charged groups via toluidine blue assay. Finally, the selected beads were employed in a protein sample derived from a bioreactor. The results obtained allowed verifying their promising use for protein adsorption separation and purification. These results suggest a promising future of sustainable polysaccharide-based beads for applications in downstreaming and purification of proteins.

Production and regeneration of sorbent material basedon kapok fibers, chitosan and castor oil: application in the cleaning of fauna affected by oil spills.

Islla Mirella Caetano Silvino[1], Beatriz Seixas Alves[1], Nathália L. P. Andrade[1], Carmem Lucia de Paiva e Silva Zanta[1], Vanderson Barbosa Bernardo[1], José Leandro da Silva Duarte[1], Leonardo Mendonça Tenório de Magalhães Oliveira[1]

e-mail: isllamcs@gmail.com

Oil spills cause negative effects on biodiversity, requiring remediation techniques for the affected fauna. In this context, natural sorbents are research targets because they come from renewable sources and its reusability is appreciated due to economic, environmental and operational factors [1]. Thus, this research produced composites of kapok fibers, chitosan and castor oil, tested them for the removal of mineral oil from goose feathers through light and shear contact, and evaluated the regenerative potential of compression techniques, with loads of 4 to 12 to centrifugation, with rotations from 500 to 2000 rpm for5 mi vacuum filtration for 5 min and photocatalysis, through impregnation with TiO2 subjected to UV for 2 hrs. These were made with unpressed (CNP) and previously pressed (CP) composites at 3 ton. The sorptions were measured by gravimetric method. The CNP showed an average sorption of 29.95±4.84 g/g and CP 21.50±2.63 g/g. Feathers saturatedwith oil resulted in 12.42±2.31 g/g sorption, where 84.98% and 82.84% of the sorbed oil was removed by the composite. At the end of the 4 compression cycles, the CNP maintained66%, 39%, 38% of the original sorption capacity for loads of 4 ton, 8 ton and 12 ton, while the CP maintained 68%, 39% and 42%, respectively. In centrifugation, at 500 rpm, 1000 rpm and 2000 rpm, the CNP maintained 61%, 95%, 93% of the original sorptive capacity, and the CP maintained 68%, 86% and 84%, respectively. In vacuum filtration, the CNP retained 97% and the CP 90% of the oil, as the vacuum generated was not sufficient to remove the oil, due to its high viscosity. The photocatalytic activity process was not effective.

e-mail: filipeh@usp.br

Polyurethanes (PU) pose an outstanding share of the plastic market, and the research for bio-based routes of PU production is an essential field of study, playing a key role in the search for a more sustainable future. This work describes the solvent-free formation of PU films simultaneously with the synthesis using castor oil (CO) and microcrystalline cellulose (MCC) as polyols [1] and an aliphatic polyisocyanate resin based on hexamethylene diisocyanate (HDIr). The films were formed from different amounts of cellulose nanocrystals (CNC) and nanofibers (CNF) in the reaction mixture. The scanning electron micrographs indicated that the films with CNC and CNF were homogeneous and presented low surface rugosity. These features influenced the mechanical properties, in which the CNC ad CNF films showed higher elongation (~50%) and tensile strength at break (~5 MPa) compared to the neat PU film (~4% and 2 MPa, respectively). The thermogravimetric analysis showed the characteristic decomposition peaks of cellulose and PU bonds, with no great difference between all the films. The contact angles of the CNC and CNF films exhibited a moderate tendency of lower angles for those containing CNF, indicating slightly higher hydrophilicity. O_2transmission rates results indicated that the nanocrystalline cellulose particles lowered the O2 permeability three-fold, with slight differences according to the amount of additive. Further studies are being performed, investigating how to coat bacterial cellulose film onto the reaction mixture, aiming to produce bio-based PUs composite-type film with good tensile and O_2permeability properties. The properties of the films containing CNC/CNF are attractive for packaging applications, among others.

Synthesized MgO polysaccharide starch-based: Periclase phase formation for chromium adsorptionand its reuse as green pigments

Nayara Balaba[1], Silvia Jaerger[1], Julia de Oliveira Primo[1], Fauze Jacó Anaissi[1]

[1]Universidade Estadual do Centro Oeste

e-mail: nayarabalaba20@gmail.com

As a nutrient found in some foods, trivalent chromium (Cr^{3+}) is more stable than the hexavalent ($Cr^{6+)}$ form, which plays an important role in glucose metabolism, but in above 1.0 $mg.L^{-1}$ it becomes harmful to health, and when left free in the environment it can end up oxidizing to Cr^{6+} [1,2]. This work aimed to synthesize magnesium oxide (MgO) in the periclase crystalline phase by the gelatinization method in a reaction medium with starch cassava. The search for natural additives, such as polysaccharides, for materials synthesis, has recently gained importance due to their reported low environmental impact, higher chemical reactivity, high combustion power, reduced calcination temperature, and action asa complexing gelling agent. Samples of synthesized and commercial. MgO (S-MgO and C-MgO, respectively) were characterized by structural characterization (XRD), composition (EDXRF), spectroscopy (UV-Vis), and colorimetry before and after chromium adsorption. In the adsorption study, S-MgO and C-MgO were investigated as adsorbents in the removal of Cr^{3+} ions from synthetic wastewater. DRX results after the adsorption process show that the periclase phase was changed to brucite with basal distance (001) equal to 0.48 nm [3], producing a green pigment. After adsorption, the hybrid pigments were dispersed in white real estate paint and tested against leaching to prove the stability of chromium ions in the magnesium oxide structure, so that materials with contaminating ions and without release into the environment have a final destination.

The impact of osmotic pressure on the water holding capacity and herbicide adsorption of new magnetic hydrogels composed of polysaccharide and zeolite supported on poly(methacrylic acid)-co-polyacrylamide networks

e-mail: tanaka.fabricio@gmail.com

In this study, novel magnetic hydrogels were synthed by incorporating unfunctionalized magnetic nanoparticles (Fe_3O_4) and 3-aminopropyltriethoxysilane-functionalized magnetite nanoparticles ($Fe_3O_4@NH_2$) into PMAA-co-PAAm polymeric networks containing CMC and zeolite, aiming their potential use in water herbicide removal systems. For this purpose, the swelling degree and paraquat adsorption capacity were analyzed in different salt media. A substantial reduction in the swelling degree values was observed in both the pure sample and the sample with Fe_3O_4, with only 38.0% and 23.5% of their respective capacity to store water molecules with the highest tested salt concentration (0.20 mol.L^{-1}of NaCl). However, the sample with $Fe_3O_4@NH_2$managed to retain around 52.3% of its swelling degree. Similarly, in the case of paraquat removal capacity, a decrease was observed with an increase in salt concentration. In pure water, all samples showed an adsorption capacity $q$of approximately 13.0 mg. g^{-1}. However, this capacity was reduced to values below 3.0 and 0.8 mg/g for solutions with 0.20 mol.L^{-1}of NaCl and 0.15 mol.L^{-1}of $AlCl_3$. This decrease in both analyses could be attributed to the interaction between the salt ions and the hydrophilic groups of the samples, leading to a reduction in the elasticity of the polymer chains. [1] Nevertheless, despite the reduction caused by the osmotic effect, all samples exhibited the ability to remove a concentration of paraquat higher than those reported in the literature, which was above the limit accepted by the OMS. [2] Thus, the findings of this study suggest that even in unfavorable conditions, the hydrogels synthed in this work, hold promise for use in herbicide removal from water.

e-mail: kamila.santos@ctec.ufal.br

Oil exploration brings environmental impacts, which end up causing oil spills which generate irreversible consequences in the affected ecosystems [1]. One of the techniques used is natural sorbents, which are mostly made up of vegetable fibers, such as sugarcane bagasse, leafy residues, sisal, coconut, sawdust and kapok fiber [2]. Therefore, the focus of this work was to promote surface acetylation in kapok fibers (Ceiba pentandra) to improve their oleophilic or oil retention character. The concentration of treatment with acetic acid solutions was varied at 1, 2, 3, 4 and 5% (v/v), with the raw samples in contact for 1 h, followed by drying at 50 °C. The sorption evaluations were carried out via gravimetric test,by initial and final mass difference after 30 min of contact time in S-10 diesel oil. The samples were characterized by FTIR and optical microscopy to assess functional and structural changes. With acetylation, there was hydrolysis of the cellulose in the fibers, making them rougher and forming a random orientation of the fibrous bundles. It was also noted that low concentrations of acetic acid led to an increase the C=O presence, and affected sorption with increase of almost 30%, and under concentrations above 2% (v/v), damage to the fibers was evidenced with the presence of folds and rupture of the tubular structures responsible by oil storage, reaching, at 5% (v/v), a sorption similar to that of the raw material.

Analysis of the influence of chitosan molar mass on quaternization process

Danielle Bitencourt Faria[1], Filipe Biagioni Habitzreuter[2], Classius Ferreira da Silva[3], Mariana Agostini de Moraes[3]

[1]Universidade Federal de São Paulo, [2]Instituto de Química de São Carlos Universidade deSão Paulo (*Departamento de Físico-Química*), [3]Universidade Federal de São Paulo (*Departamento de Engenharia Química*)

e-mail: danielle.bitencourt@unifesp.br

Chitosan is one of the most studied biopolymers in the world, especially due to its cationic character and biological properties. However, chitosan is only soluble on a limited acidic pH range. To improve chitosan solubility in a broader pH range and increase its applications, chemical modifications can be performed, as the quaternization process, where functional groups are introduced by substitution or addition in organic compounds [1]. It is known that chitosan molar mass affects the crystallinity, solubility, permeability and mobility of the molecular chains, however, there is a lack of studies in the literature that analyzed the influence of chitosan molar mass on the quaternization process and on the final product properties. In this study, chitosan quaternization with GTMAC was assessed with chitosan of three different molar masses and analyzed regarding quaternization degree, deacetylation degree and thermal stability. It was possible to observe that the degree of quaternization increases with the increase in chitosan molar mass, while the acetylation degree increases in a similar manner when compared to the non-quaternized chitosan, regardless the chitosan molar mass. Regarding the thermogravimetry, the peaks related to thermal degradation were observed on a lower temperature for the quaternized chitosan, and increasing chitosan molar mass decreased the temperature of thermal degradation. In conclusion, it was possible to observe that the molar mass is a key factor on chitosan quaternization and should be taken into account on studies and new technologies applied to chitosan materials.

Polysaccharides may have antioxidant, anti-inflammatory and immunoregulatory properties making them suitable when used in biological systems [1]. Biocomposites based on clays and biopolymers are materials of increasing biological interest as they show improved mechanical and physicochemical properties [2]. The use of clays as a support can increase the stability of dyes mainly due to the adsorption and intercalation capacity of organic molecules [3]. Therefore, this work aimed to develop a new stable hybrid from the incorporation of quercetin in cashew gum-modified Laponite. The solids obtained were characterized by XRD, Infrared and SEM analysis. The antimicrobial activity for possible biological application was evaluated. The results indicated high intercalation of quercetin in the modified inorganic matrix and good antibacterial activity against Staphylococcus aureus and Escherichia coli strains. This initial research shows the potential for using the nanocomposite in safety-sensitive applications.

The increasing popularity of biopolymer-based packaging is attributed to their eco-friendliness, non-toxicity, and biodegradability, providing a promising alternative to synthetic materials[1]. Chitosan, a biopolymer with excellent biodegradability, environmental benefits, antimicrobial properties, and film-forming ability, has been widely studied for its potential as a packaging material [1]. However, its weak mechanical and barrier properties restrict its application[1]. In this research, we aimed to address this limitation by incorporating kraft lignin carbon dots into chitosan films via a simple method without plasticizers. Our approach involved adding 20 mL of 1% acetic acid to 0.2 g of chitosan and stirring it in an ultrasound tip until dissolution, followed by adding 100 uL of lignin kraft carbon dots doped with ethylenediamine. The mixture was then transferred to a polystyrene petri dish and dried in an oven at 65ºC for 24h. We conducted stress tests, FTIR, and thermal analysis to evaluate the resulting films. The films were easy to demold and exhibited a blue-green color when exposed to a light beam in the ultraviolet region (360nm), suggesting a possible photoluminescence effect from the carbon dots. The tensile strength result of 37 MPa was promising, and FTIR analysis indicated hydrogen bonding between the single OH bonds of chitosan and carbon dots. The shift in the CH peak to 1648 cm −1 indicated increased elongation C=C. Thermal analysis revealed changes in the thermal profiles of the samples with carbon dots. Therefore, our study demonstrates the potential of developing films with desirable properties using chitosan and carbon dots.

e-mail: bianca.godoy@ctec.ufal.br

In 2019 there was an oil spill in Brazil that reached the coastline of 4,334 km in 11 states in the Northeast and Southeast. From this perspective, biosorbents have been highlighted as a method for removing organic contaminants, since low-cost, abundant, and biodegradable biomasses are used [1]. Therefore, the present work evaluated the sorptive capacity of natural materials taken as agricultural residues from the Brazilian northeast, such as, kapok fiber, coconut palm straw, natural and washed sugar cane straw and bagasse, corn cob, emu shank and cassava husks, simulating their uses for remediation of spills of Lubrax 20W50 motor oil, S-10 diesel and API 29 petroleum. The sorption tests were performed using an evaluation of the relative difference in mass between the initial sorbent sample and after contact with the oil, varying this time from 1, 5, 10, 15 to 30 min. Analogously, an oil capture stability test was carried out, where the sample was directed to a Shaker incubator to be shaken under rotation of 150 rpm during times of 5 and 10 min, calculating the sorption by the relative difference again. Optical Microscopy was performed to evaluate the characteristics of the structures of the materials. It was observed that emu shank, sugar cane bagasse, coconut palm straw, corn cob and kapok fibers needed to remain in contact with oil for 30 min so that there was a greater passage of oil between the structures of the samples. On the contrary, cassava peel and sugarcane straw needed only 1 minute to reach equilibrium. In addition, sugarcane bagasse, coconut palm straw and kapok should be given greater attention to oil release and possible contamination, since they had more significant oil losses between the times of 5 and 10 minutes, being 70, 17 and 15%, respectively.

e-mail: anisio.evilasio@gmail.com

Pineapple (*Ananas comosus L.*) leaves are a significant waste product generated after fruit harvesting, resulting in a considerable amount of biomass available for use. The fibrous material obtained from pineapple leaves exhibits a higher cellulose content than wood fibers and a lower lignin content than other commonly used alternative fibers such as palm and coconut[1]. Therefore, this agro-residue has great potential as a reliable and sustainable source of cellulose for producing a wide range of derivative products. However, a bleaching process is necessary to improve the quality of the obtained pulp. In this study, pineapple leaves were milled and subjected to a bleaching process using a hydrogen peroxide and acetic acid (HPAC) solution at a 1:1 ratio. The process was conducted in an oven at 80°C for12 hours. The obtained pulp was then neutralized and dried. To evaluate the efficiency ofthis process, infrared spectroscopy (FT-IR) and X-ray diffraction (XRD) were performed. TheFT-IR analysis indicated a reduction of absorbance in lignin (1595 cm^{-1}) and hemicellulose(1730, 1625 cm^{-1}) characteristic bands[2] after the HPAC treatment. The crystallinity indexeswere determined using the method described by Sang Youn O *et al.* (2005). The "in nature"PLP had a crystallinity index of 15%, while the bleached PLP had a crystallinity index of17%. Based on the results, it can be concluded that the HPAC treatment effectively reducesthe hemicellulose and lignin contents present in the pineapple leaf powder. However, the treatment does not appear to have a positive effect on removing amorphous regions, indicating the need for additional treatment.

The use and development of biopolymers as mechanisms for releasing bioactive compounds have shown to be quite promising due to their compatibility with the environment and high bioavailability [1]. Among them, cassava gum stands out, a polysaccharide obtained from the tubers of ***Manihot esculenta***, which contains 80 to 86% starch in its composition and presents excellent hydrogel formation capacity [2]. This work aimed to synthesize hydrogels from cassava gum associated with nerolidol and study their antibacterial activity. The direct contact method characterized the material by FTIR and antibacterial activity. The characterizations confirm the formation of the hydrogel and the presence of nerolidol in its matrix. The antibacterial activity against ***S. aureus***and ***E. coli***was satisfactory with hydrogels containing concentrations from 2% of nerolidol, showing an 80% effect on their activity. The formation of hydrogels proves promising for the release of bioactive compounds.

e-mail: isaacmoura@cear.ufpb.br

Lignocellulosic biomass (LCB) is an energy source of great impact in today''s world and can be used as a raw material in the production of biofuels and value-added compounds [1]. Thus, the objective was to verify the technical feasibility and potential of using biomass energy from banana peel residues based on the physical-chemical characterization as a possible alternative in the production of biofuel and briquette. Prior to characterization, a pre-treatment process was performed to obtain banana peel powder. The powder was then analyzed for ash content, higher calorific value (according to ASTM D5865-13), FRX, and TG. Ash content was determined to be an average of 13.95±0.065% per gram of powder. The study also measured the calorific value, which represents the energy produced as heat during the energy conversion process. The calorific value was found to be 16960±244 KJ/Kg. As for the FRX analysis, the main elements detected in the residue (powder) were K_2O (56.56%), CaO (12.52%) and SiO_2 (7.19%). Regarding the thermogravimetric profile, a significant mass loss event was observed starting in the temperature range of 148 °C and mass of 97.23 %, reaching the end of the event at about 523 °C and mass of 37.43 %, realizing a loss of 59.80%. This can be attributed to volatilization and degradation processes of the main components of lignocellulosic biomass (cellulose, hemicellulose and lignin). Based on the excellent results obtained, it is concluded that waste from banana peel is a possible alternative in the production of biofuel and briquette.

e-mail: karielly059@gmail.com

Lobeira starch (S. lycocarpum) is a polysaccharide widely distributed in Brazil, with relevant attributes for the production of thin films with compatibility and biodegradability. This study aimed to develop biodegradable films of Lobeira starch and evaluate the water vapor barrier properties, moisture content, water solubility, and UV/Visible light transmission. The biodegradable films were developed according to the casting technique, with starch gelatinization in water (4%) for 30 minutes at 80 ºC, glycerol was added as a plasticizer (0.25 g g-1 of starch) [1,2]. The starch extracted from Lobeira fruits presented a visual aspect similar to commercial starch, with obtaining films of continuous structure, flexible and without the presence of cracks, a behavior associated with the plasticizing effect of glycerol on the polymeric matrix. Moisture content (22.05 ± 0,12%), water solubility (29.94 ± 0,2.45%), water vapor permeability (0.42 ± 0.001 (g.mm.KPa-1.h-1.m-2), and light barrier were similar to those described for films obtained from starch from different sources, such as cassava. Thus, according to the results obtained, the starch extracted fromLobeira fruits can be a potential biopolymer for the development of biodegradable films oredible coatings for food, in addition to acting as a carrier of natural bioactive compounds forthe development of active packaging.

Cellulose/PVA/chondroitin sulfate membranes: Study of thermal stability and release of paracetamol

Blends of cellulose/polyvinyl alcohol/chondroitin sulfate (cel/PVA/SC) have been highlighted for expand the applications of cellulose in the form of membranes, improving their physical characteristics, such as thermal stability and drug release [1]. In this work were produced ternary blends of cel/PVA/SC cross-linked with epichlorohydrin with different compositions of SC and incorporated with paracetamol. The membranes were produced by the casting technique from mixtures of aqueous solutions (3% w/v) of PVA and SC and alkaline (NaOH/urea) of cel. The membranes were characterized by FT-IR, TGA and DSC while the paracetamol release kinetics was evaluated using a Franz cell. FT-IR results showed shift of OH bands indicating cross-linking of cel/PVA/SC membranes. TGA/DTG and DSC analysis showed that increasing the amount of SC caused a decrease in the degradation temperature and indicating a reduction in the thermal stability of the membranes. The release kinetics were evaluated by Korsmeyer Peppas, Peppas Sahlin, Weibull, Lindner and pseudo-First Order models. The results showed that the kinetics data fit better to the empirical Weibull model. The parameter b of the Weibull equation indicates a mechanism of paracetamol release controlled by Fickian diffusion (0.35 smaller b smaller 0.75)[2]. Abstract:
One of the by-products generated after ginger starch (GS) extraction consists of a fibrous material containing cellulosic fibers and residual starch. This mateiral is denominated ginger bagasse (GB). This study aimed to characterize the ginger bagasse (GB) concerning chemical composition, structural and morphological aspects, and initial studies about bleaching. Ginger processing waste has been used as a bioabsorbent for the treatment of water used in textile industries that uses malachite and methyl violet dyes [1,2]. In this work, we focus on the characterization of this material for the future obtainment of cellulosic nanostructures and their applications as reinforced polymers in the context of sustainable materials developing from biomass attributing added value to this kind of agro residue. The initial results indicated success in obtaining cellulosic material with a lower teor of residual starch and fibers rich in cellulose (TAPPI T13m-54, TAPPI T19m-54, and TAPPI T19m-54 standards) - 48.41 ± 2.93%. The original morphology (investigated by Scanning Electron Microscopy) showed that the presence of vegetal cells reinforced the necessity of the bleaching process.

Acknowledgments:
The authors would like to thank SISNANO/MCTI, FINEP, Embrapa AgroNano research network and the National Nanotechnology Laboratory for Agribusiness (LNNA) at Embrapa Instrumentation and the Federal University of Technology - Paraná and Federal Universityof Mato Grosso (UFMT- CUA) for the general facilities.

Propolis is a complex mixture of resinous substances collected by bees (Apis mellifera) from different plants, which allows its consistency, texture, and color to vary [1]. Scanning Electron Microscopy (SEM) allows for reaching magnifications greater than 10,000 times Optical Microscopy [2]. It is the most suitable technique for microphotographs of samples, due to the depth that the electrons can scan [2]. The objective of this work was to characterize microspheres containing red propolis with sodium alginate by SEM. The study took place in the microscopy laboratory at the IFAL Campus Maceió. A Vega 3 TESCAN apparatus was used, operating at 15 kV, with increments of x100, x200, x500, x1000, x2000, and x5000, to obtain photomicrographs of the tested formulations, with a working distance of 15.97 mm. The results of the 8 treatments demonstrated, in general, that a good part of the microspheres presented spherical shapes and, with some fissures, grooves, and/or depressions in their external walls. In formulation H, better morphology was verified, being more defined and compatible with the shape of microspheres for the use of the material as a nanocarrier of active substances.

e-mail: mvwbarcote@gmail.com

Currently, the use of harmful materials to the environment in the manufacture of devices is considered one of the significant challenges when developing electronic devices, thus the search for new substrates for flexible electronics, in general, has intensified. The material used here as the substrate is based on chitosan, a biopolymer from the polysaccharide family, obtained through the deacetylation of chitin (chitin is the second most abundant natural biopolymer on earth, second only to cellulose). In this work, we developed new flexible substrates based on chitosan and studied depositions of organic semiconductor materials dispersed in aqueous media, such as PEDOT:PSS. Here, the slot-die coating technique was used to deposit reproducible thin chitosan films, producing thin films with controlled thicknesses of ≅ 10 µm. The relationship of stability of chitosan substrates through wettability was analyzed, revealing a hydrophilic characteristic in relation to the time of 5s. The optical properties studied are through scanning electron microscopy (SEM) of thin films in which the morphological properties are reviewed, exposing its smooth andcontinuous surface. The mechanical and electrical properties are studied through the bending method, to obtain the resistance in relation to the flexibility of the conjugatedpolymers on top of the chitosan substrate. As an application for this work, biodegradablegas sensors for ammonia detection are developed. This work can contribute to the futuredevelopment of sensors for the detection of ammonia gases, thus expanding the applicabilityof the composites used.

Creating 3D Highly Porous Interconnected Bacterial Cellulose-based Architectures Through Bioconfinement Engineering for Health Sciences

Ana Carolina Aguiar[1], Filipe Vargas Ferreira[1], Liliane Maria Ferrareso Lona[1]

[1]Universidade Estadual de Campinas (*Faculdade de Engenharia Química*)

e-mail: carolinadeaguiar96@gmail.com

Nanocellulose membranes derived from bacteria, known as bacterial cellulose (BC), have attracted great attention in biomedical applications due to their outstanding properties, such as biocompatibility, high purity and porosity, good water holding capacity, and high mechanical strength. In addition, the intertwined chains of this polysaccharide resemble the structure and dimensions of collagen networks, making it an excellent candidate for wound dressings and tissue engineering. While the traditional synthesis method can produce mechanically robust hydrogel fibrous structures based on cellulose, we have proposed an innovative platform with remarkable properties and features. We employed bioconfinement engineering to construct highly porous, interconnected three-dimensional (3D) architectures. Specifically, superhydrophobic particles (*i.e.*, polytetrafluoroethylene – PTFE), are utilized to restrict the growth of nanocellulose-producing bacteria (*Komagataeibacter medellinensis*) in a culture medium, forming the called liquid marbles. After 5 days, PTFE particles are removed, producing highly porous BC capsules. This method enables the synthesis of biomaterials with high water content and precise control over thickness, morphology, shape, and compartmentalization. The variables that influence the conformation and in-situ growth of 3D attractive objects (*e.g.*, incubation time, the of the particles used for bioconfinement, volume of culture medium, ambient temperature and humidity during the process) are discussed in detail with respect to the air-water interface. Promising results are presented for several advanced implications in health sciences, particularly in tissue repair and regenerative medicine. In conclusion, our bioconfinement engineering method has the potential to pave the way for the development of novel biomedical devices through easy and scalable production cycle.

Development of a controlled-release device fortreatment of periodontal disease based on thermoplastic starch and chlorhexidine

e-mail: camilafgerardo@gmail.com

Periodontal disease is an infectious-inflammatory disease that affects the supporting tissues of the teeth. It is characterized by loss of attachment of the periodontal ligament and destruction of adjacent bone tissue, which may lead to tooth mobility and, in more advanced stages, to tooth loss [1]. Treatment requires the removal of bacterial plaque through non-surgical mechanical treatment of crown and root scaling and planning [2]. Adjuvant therapy to mechanical treatment, using antimicrobials, has been suggested in order to prevent the recurrence of the infection [3]. The aim of this research is develop a controlled-release device to be used as an adjunct to the treatment of chronic periodontal disease. In this work, Thermoplastic cornstarch (TPS) films with chlorhexidine were prepared by casting in different percentages (0.5, 1, and 2% m/m) nanoparticles of clorexidine (CHX). The films were covered with a layer of hexamethyldisiloxane (HMDSO) plasma to evaluate their physical-chemical performance and compare these results with films without HMDSO plasma. The morphological characterizations were carried out by SEM and AFM, showing good adhesion of the nanoparticles to the thermoplastic matrix, corroborating the FTIR results. Tensile properties were statistically evaluated using the Kruskal-Wallis and Dunn tests. The incorporation of nanoparticles of CHX did not lead to significant changes in strength, maximum stress and strain at break. The highest modulus of elasticity values was found for the TPS. The films TPS/CHX showed good mechanical chemical, and morphological performance, proving to be promising to be used as an adjunct to the treatment of chronic periodontal disease. Acknowledgements:
Faperj

e-mail: sidney.souza@unesp.br

Due to its unique characteristics, such as high crystallinity index, porosity and biocompatibility, bacterial cellulose (CB) has been explored in several areas1. Silver nanoparticles (AgNPs) are known for their bactericidal properties and currently alternative methodologies have been gaining prominence, such as the use of plant extracts as reducing and stabilizing agents2. The present work aims to produce a biofilm from the combination of AgNPs obtained through the plant extract of tucumã (Astrocaryum aculeatum) with bacterial cellulose prepared from commercial fermented teas (kombucha). For the production of CB, green tea was used as a growth medium and later refined sugar was added with the addition of the propagation matrix (Scoby). For the preparation of AgNPs, 5 mL of plant extract and 50 mL of $AgNO3$ (0.1 mol L-1) were mixed with the reaction medium at pH 9.0. Then the BC (2x2 cm2) was added in the dispersion of AgNPs in aqueous medium. The UV-VIS technique was used to observe the alteration of the intensity of the plasmon band of AgNPs. UV-VIS analyses showed a gradual decrease of the plasmon band from the first to the seventh day of reaction (0.68-0.38) and also a blue shift in the maximum intensity of the silver plasmon band. Additionally, SEM results confirm the incorporation of these AgNPs in the BC surface. The results suggest that AgNPs are adhering to the surface of the biofilm, however, there is possibly a greater incorporation of larger particles into the membrane. Antimicrobial activity was detected against E. coli and S. aureus.

The emergence of the COVID-19 pandemic has highlighted the need for effective personal protective equipment, particularly face masks, to limit the spread of the virus. However, contamination of masks through interpersonal contact or handling poses a challenge that requires the development of bioactive textile coatings that reduce the need for mask changes and increase user protection. In this study, we report the development of polypropylene masks coated with organic antimicrobial agents, including polyethyleneimine (PEI), lauric acid (Lau), besides Cu2+ salts, and their virucidal performance against coronaviruses. The materials were characterized by Water Contact Angle and X-ray photoelectron spectroscopy (XPS). Coating virucidal performance was tested against coronaviruses (MHV-3 strain) and the cytotoxicity to L929 control cells as previously reported [1]. Water contact angle and XPS results validated the masks surface modification. The virucidal results showed that the PEI and Lau coatings led to significant viral titer reductions of 99% to 99.99% after 2 h of contact with the virus. Furthermore, the PEI coating associated with copper salt exhibited rapid action, with a viral inhibition from 99.9% to 99.99% in less than one minute, indicating that CuSO4 can improve the virucidal effect of the coating on a large scale. Although the coatings demonstrated virucidal kinetics performance compared to other antiviral coatings, the presence of copper ions potentializes their effect, promoting the virus inactivation in less than one minute. This hybrid coating proves to be a suitable candidate for applications on masks for rapid inactivation of the virus, thus contributing to the development of effective personal protective equipment in the fight against the COVID-19 pandemic.

The presence of dyes in water is one of the main sources of pollution and represents a major environmental concern, promoting the search for new adsorbent materials to treat industrial effluents [1]. In this sense, this study aimed to produce hydrogels based on polysaccharides: cellulose/alginate (CEL/AL) and carboxymethylcellulose/alginate (CMC/AL) for removing methylene blue dye (MB) in aqueous medium. The hydrogels were produced from solutions of CEL, AL, and CMC, with 50/50 (w/w) proportions of the polymers and gelled in calcium chloride solution (1% m/v). Scanning electron microscopy (SEM) analysis showed that the CEL/AL 50/50 hydrogel has an irregular spherical external morphology, while the CMC/AL 50/50 has a more compact surface. The MB dye removal capacity was up to 77.79% for the CEL/AL 50/50 hydrogel and 67.30% for the CMC/AL 50/50. The non-linear Freundlich model had a better fit for the CEL/AL 50/50 hydrogel, showing a favorable sorption with the n constant within the range of 1 to 10 and an R2 of 0.979, indicating that the adsorbent surface is heterogeneous and that has adsorption sites in different layers. for the CMC/AL 50/50 hydrogel, the Sips model provided an R2 value greater than those found in the Freundlich and Langmuir adjustments, with an n value greater than 1.0 (n = 4.117), indicating that simultaneous adsorption may occur in mono and multilayer [2]. Acknowledgments: this work was carried out with the support of the Coordination for the Improvement of Higher Education Personnel-Brazil (CAPES) and Fundação Araucária/Brazil. e-mail: jonasbarbosa@alunos.utfpr.edu.br

The preparation of fluids used in the primary cementing process of oil wells is a critical step. These fluids are responsible for promoting better stability and safety of the well. In general, the preparation of drilling fluids and spacer fluids requires complex formulations with several abrasive additives, which increases its difficulty to dispose of. Aiming to develop drilling and spacer fluids with rheology compatible with the specifications provided by PETROBRAS, two fluids with simpler formulations were developed, in order to represent the behavior of field fluids. The spacer fluid is water-based, while the drilling fluid is soybean oil-based. The preparation of the spacer fluid is done by adding the additives Xanthan Gum, HPMC, and salt and then stirring until fully dissolved. The oil-based drilling fluid was prepared similarly, using EVA (ethylene-vinyl acetate), a copolymer used in lubricants, as the main additive. The use of EVA replaces the use of bentonite, barite and microemulsions, which add complexity to the formulation and require furthermore concern in its disposal. Rheology tests were performed using a Fann Model 35A viscometer and a Mars III Rheometer, which provided data to evaluate behavior curves to indicate similarity with the fluids used in the field. The results obtained for both fluids were acknowledged as non-Newtonian behavior curves according to a Herschel-Bulkley fluid, demonstrating a close rheology with PETROBRAS field fluids according to graphics and comparative tables for tension, shear rate and viscosity. Therefore, based on the rheology results obtained, the formulated fluids were considered suitable for conducting tests that simulate primary cementing, with the advantage of their less complex, non-abrasive formulation, potential for reuse, and ease of disposal.

Hydrogels classified as superabsorbents have great potential for applicability, from agriculture to environmental remediation [1]. It is due to the water retention capacity hundreds of times, thus allowing a prolonged water supply to the crop through the plant roots and beyond the control of release in the soil [2]. Thus, hydrogels were developed using highly available natural sources in the Northeast region, such as chicha gum (*Sterculia striata*) copolymerized with acrylates, for application in agriculture. The hydrogels were characterized by X-ray Diffraction (XRD), and changes were observed in the semi-crystalline profile of the hydrogel with the insertion of potassium phosphate and chicha gum. In the results through Fourier transform infrared spectroscopy (FTIR), the characteristic bands of the formed polyacrylamide, interactions with chicha gum, and the presence of phosphorus bonds coming from the fertilizer. In the results obtained by Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS), changes were observed in the material's morphology and evidence of the presence of potassium phosphate in its structure. In the swelling results, it was observed that the hydrogels have characteristics of superabsorbents, with the best swelling for the material formed from polyacrylamide and chicha gum in the proportion of 2.0/0.01 (w/w), with values of 36000.00% of swelling concerning the initial weight of the hydrogel.

Acknowledgments: The authors thank CAPES, CNPq, and FAPEPI.

The indiscriminate disposal of toxic metal ions in water resources has been a risk to human health due to contamination of living organism through food chain. The biodegradable adsorbents are an alternative renewable, sustainable, economical, for wastewater treatment. This study investigates the effect of magnetite (MAG) incorporation in cellulose (CEL) and alginate (ALG) matrices for cadmium (Cd^{2+}) adsorption. The MAG synthesized by co-precipitation was dispersed in the proportion of 30% (w/w) in the polymer solutions 3% (w/v). CEL and CEL/MAG beads were prepared by dripping in $H_2SO_4$10%(v/v) solution and ALG; ALG/MAG; CEL/ALG and CEL/ALG/MAG by ionic gelation in $CaCl_2$3% (w/v). The beads were characterized by XRD, swelling capacity (SW) and Cd^{2+}ion removal efficiency. The additional ALG cross-linking provided by Fe^{2+}/Fe^{3+}ions from MAG is responsible for the lower SW values in beads containing ALG [1]. The highest SW values were observed for the CEL (61.85%) and CEL/MAG (70.13%) beads, attributed to the large availability of CEL and MAG hydroxyls for interaction with water. Beads with ALG have a Cd^{2+}removal range between 48.76% and 99.93%. Removal is related to the amorphous property of the adsorbents and the effect of ion exchange between $Ca^{2+}$and Cd^{2+}[2]. The highest crystallinity of the CEL and CEL/MAG beads (78.68% and 41.44% respectively) hinder the access of the adsorbate to the active sites of the adsorbent, resulting in a lower efficiency of Cd^{2+}removal (19.35% and 11, 70% respectively) [3].

e-mail: ucmruschoni@usp.br

The occurrence of hydroxycinnamic acids (ferulates and p-coumarates) in xylan molecules extracted from grasses can be explored for laccase-mediated enzymatic cross-linking of the polymers. Lignin fractions and lignin-carbohydrate complexes contaminating xylan preparations also serve as substrates for laccase-mediated oxidations. In both cases, the increased molar mass of the polymers is expected in the reaction products, which present potential applications for the preparation of polysaccharide hydrogels and adhesives. The current work aimed to extract and transform xylan fractions from two different grass biomass materials (sugarcane bagasse and corn stover). Extracted samples were treated with laccase targeting cross-linked products. Sugarcane bagasse and corn stover, previously ground in ball mills to increase enzymatic digestibility, were treated with alkaline xylanases. Extracted xylans were recovered at 13.2% (m/m) and 14.3% (m/m) yield, respectively. Ferulate (FA) content in extracted xylans corresponded to 1.8 FA/100Xyl and 2.3 FA/Xyl, respectively. After laccase treatment, both samples presented increased molar mass in the polysaccharide and aromatic fractions. Accordingly, phenolic hydroxyl contents decreased in both samples: 0.73% to 0.16% in sugarcane xylan and 0.58% to 0.34% in corn stover xylan. Both data suggest that phenolic groups were oxidized by laccase treatment resulting in cross-linked products with increased molar mass.

Evaluation of polyelectrolyte complexes based on sodium alginate and chitosan designed for targeted colon delivery.

Amanda Letícia Polli Silvestre[1], Aline Martins Santos[1], Andreia Bagliotti Meneguin[1], Marlus Chorilli[1]

[1]Faculdade de Ciências Farmacêuticas, Campus de Araraquara, UNESP (*Fármacos e Medicamentos*)

e-mail: amanda.silvestre@unesp.br

Polymeric nanoparticles (NP) are being studied increasingly due to their benefits, such as nanometric, controlled release, improving the solubility and stability of hydrophilic and lipophilic active substances, vectorization, and minimizing side effects. Both chitosan (CS) and sodium alginate (SA) are used to obtain NP due to their natural, non-toxic, biocompatible, biodegradable, and mucoadhesive properties[1]. Polyelectrolyte complexation (PECs) involves interactions between polyelectrolytes with opposing charges by supramolecular interactions between CS and SA [2]. NP anionics can be beneficial sincethey adhere to positively charged proteins in inflamed tissues and can be strategic for inflammatory bowel diseases (IBDs), which are characterized by chronic inflammation in the mucosa of the gastrointestinal tract, mainly in the colon region. Mesalazine (MLZ) is an anti-inflammatory medication, but its limited solubility prevents it from reaching the colonial region [3]. This study aims to evaluate how the development of QS and SA-based PECS is impacted by pH, polymer ratio, and sequence of addition. It also assesses methods that investigate how pH affects zeta potential in polymer dispersions and MLZ as a tactical tool for colon-specific release. The results showed that the order of addition had an impact on the of NPs, while NPs with higher concentrations of polycation formed aggregates and/or s with larger PDIs, while an excess of SA decreased the and PDI of the NPs. The chart of zeta potential in relation to pH showed a useful tool for selecting the appropriate pH for the creation of PECs.

Melanoma are the most aggressive skin cancer type with highest lethality. The treatment is still a challenging issue because the systemic toxicity and drug resistance. The use of less toxic compounds can bring strategic solutions. Sulfated polysaccharides are an example of this compound, as a Fucan A extracted from a species of brown seaweed that showed antitumoral effect [1]. To refine treatments for cancer, some questions must be raised: How to target this compound to the tumor microenvironment, thus avoid systemic loss of the compound and reduce the dose for therapeutic? Looking for alternatives to answer these questions, nanoparticles use becomes interesting. In recent years, studies in nanomedicine have demonstrated the great potential of using these nanoparticles to treat different diseases, especially cancer. The objective of this work is to obtain gold nanoparticles functionalized with Fucan A and to evaluate its antitumor activity in cell culture and in animal model. The synthesis method selected to obtain the nanoparticles presents high yield, easy reproducibility and guarantees very stable dispersions for long periods. The characterization of the functionalized gold nanoparticles was performed using UV-visible light spectroscopy, transmission electron microscopy, dynamic light scattering, Fourier transform infrared spectroscopy. Nanoparticles do not show cytotoxicity for non-tumor and tumor cells and seem to be able to modulate the tumor malignancy profile by altering the invasive and migratory capacity of melanoma cells. Nanoparticles with Fucana A conjugated to a fluorophore were also obtained to evaluate the action mechanism of nanoparticles in melanoma cells. The results have shown that nanoparticles functionalized with Fucana A have great potential for therapeutic application, enhancing the antimelanoma action of this polysaccharide.

The search for replacing petrochemical plastics by biopolymers has been increasing every year due to environmental issues. One of the disadvantages of biopolymers is that these materials are highly hydrophilic. Some additives are used to modify the hydrophilicity of films [1,2,3], which may also influence their solubility and color parameters. Based on this, this study aimed to verify the influence of the surfactant SSO (saponified sunflower oil) on the solubility and color parameters of cassava starch films. The films were prepared by solubilizing cassava starch in water, at a concentration of 2%, under agitation, at a temperature of 70°C, until the formation of gel. In addition to glycerol, used as a plasticizer,at a concentration of 20%, on a dry basis, the surfactant SSO was also added, at a concentration of 1 and 3%, on a dry basis. The filmogenic solutions were deposited in rectangular petri dishes and placed in an oven at 50°C for 5 hours. The formed films were submitted to solubility and color analyses. The results showed that the action of the surfactant on the films did not significantly influence the color parameters and solubility of the films.

Adhesives play a vital role in a range of industries, including packaging, construction, and healthcare. However, traditional adhesives often contain harmful chemicals and are not biodegradable, leading to environmental concerns. Zein protein offers a promising solution to these issues due to its unique properties such as biocompatibility, biodegradability, low toxicity, and good adhesive properties. In recent years, researchers have explored the potential of zein protein as a sustainable and eco-friendly alternative to traditional adhesives. Zein protein-based adhesives have shown good adhesion properties on various surfaces such as paper, cardboard, glass, metal, and wood [1,2]. In this study, we used a low-cost scalable process for raw zein extraction from corn gluten meal 60 percent, and developed zein-based adhesives by chemical modification. Zein was characterized by biuret test, TGA, DSC, and UV spectrophotometry (270 nm). Adhesives were prepared by dissolving the raw zein into sodium dodecyl sulfate aqueous solution (200 mmol/L), and treated with two different metal chloride aqueous solutions ($FeCl_3$ and $CaCl_2$). Adhesive bond strength was measured in paper card (276 g/m^2grammage) using an Instron UniversalTest equipment. Results showed good adhesive strength for both metal cations, confirmingthe potential of zein as an eco-friendly alternative to traditional adhesives.

e-mail: jordane.rodrigues@ufvjm.edu.br

Woman population are the higher number in Brazilian communities (over 50 %). In this context, this Glendale has several health problems caused by different factors, such as social inequalities, family' s responsibilities, and others. [1]. Nowadays, innovative materials based on hydrogels are used to treat diverse diseases. These hydrogels are a three-dimensional network with an incredible capacity to adsorb huge amount of fluids and remain these chemical structure stable [2]. In addition, in these networks it is possible to incorporate nanoparticles that can improve several properties, such as luminescence. In this sense, the carbon dots became a new "star" of Carbon Family, above all when they are produced using a green and low-cost chemical route. Considering that, this research produced new nanocomposite hydrogels based on carboxymethyl cellulose (CMC) incorporating carbon dots performed by an eco-friendly and low-cost chemical route for woman health treatment. These hydrogels were fully characterized by FTIR, UV Visible,XPS, XRD, PL spectroscopies, SEM, and TEM. Moreover, swelling and gel-fraction were evaluated. Furthermore, cytotoxicity and fluorescence based on microscopy confocal were performed. The results showed that the main chemical groups stabilized the carbon dots in CMC were hydroxyl groups. Additionally, the morphology of hydrogel presented a homogeneous spread of carbon dots, as the biological analysis showed a uterine cancer detection based on bioimaging. Then, these nanocomposites hydrogels showed a great potential for applications in Woman health treatment.

Solanum lycocarpum starch : extraction, characterization and use in the development of films

KARIELLY PEREIRA MONTEL[1], Ricardo Stefani[1]

[1]Universidade Federal de Mato Grosso

e-mail: karielly059@gmail.com

Polymers are sustainable, technological and economic alternatives, intended for the production of films with applications in food industry, medicine, engineering as well as other áreas. This work aimed at the extraction and characterization of native starch from Lobeira(Solanum Lycocarpum), as well as the development of biodegradable films based on this biopolymer. Films were characterized with the following techniques: scanning electron microscopy (SEM), swelling, thickness , and FTIR spectroscopy. The combination of biopolymers (PVA + starch) led to thin films of high transparency with a thickness of 55.93 ± 4.14 µm. As for the FTIR of starch, there was the presence of a broad band at 3277 cm −1 , typical of the −OH bond elongation vibration, common in native starches, as well as peaks at 1149 cm −1 , 1077 cm−1 and 997 cm −1 associated with the COC and C−OH bond elongation vibratio of polysaccharides. In the FT-IR spectra of films, an increase in the −OH band of about 3200 cm was observed, related to the interaction between the −OH groups of PVA and starch. An increment of the bands at 1149 cm −1 − , 1077 cm −1 and 997 cm −1 , related to the COC and C−OH stretching vibration of the glycosidic bonds was also observed. In terms of swelling, rapid swelling of the films was observed after 5 minutes of contact with water, after which it occurred slowly up to 10 minutes, with maximum of 59.3%. This behavior may be associated with the hydrophilic characteristics of PVA and starch. Spectra indicate the starch as type B, with a high amylose content. There is indication of good compatibility between the polymers, which opens the possibility to use and apply it as biodegradable packaging.

Monascus-Derived Pigments as a Sustainable and Eco-Friendly Colorant for Textiles and Thermoplastic Materials

Silvio Silverio da Silva[1], Salvador Sanchez-Munoz[2], Tábata R. Moraes[2], Felipe A. F. Antunes[2], Thercia Balbino[2], Julio César dos Santos[2]

e-mail: silviosilverio@usp.br

Monascus biopigments have been widely used in various industries due to their naturalorigin, stability, and color quality. In the textile industry, they are utilized as a natural dyefor fabric coloring, providing eco-friendly alternatives to synthetic dyes. Monascuspigments have also been employed in the production of thermoplastic materials, such aspolypropylene and polyethylene, to improve their color properties. This work showed thepotential of Monascus pigments produced in sugarcane bagasse hemicellulosic hydrolysatesas colorant alternative for different areas. The produced pigments derived from sugarcanebagasse hemicellulosic hydrolysates showed high thermal stability (7.213 Kcal.mol -1).Additionally, these biopigments have shown potential in the development of activepackaging materials, as they possess antioxidant and antimicrobial properties that canenhance food preservation. Overall, the application of Monascus biopigments in differentindustries is a promising and sustainable approach towards achieving a greener future.

e-mail: nathalia.cunha@ufvjm.edu.br

Among several natural polymers, cellulose and its derivatives have been widely used in the production of hydrogels [1]. Hydrogels are three-dimensional structures capable of absorbing large amounts of fluids. In addition, they can incorporate nanoparticles to improve important characteristics, such as mechanical behavior, thermal and electrical properties [2]. One of these very interesting nanoparticles are cellulose nanocrystals (CNs), which have interesting properties, such as biocompatibility, biodegradability, low density, high mechanical and chemical resistance, high crystallinity and high surface area, makingthem interesting for various applications [3] . The most used extraction process of CNs arechemical routes based on strong acids that cause the hydrolysis of the amorphous region ofcellulose. In this sense, this research carried out a synthesis of hydrogels based on CNsincorporated with carboxymethylcellulose (CMC) produced by two chemical routes from afiber from the Brazilian semi-arid region. These hydrogels were characterized using FTIR,UV Visible, XRD spectroscopy, SEM and TEM. In addition, swelling and gel fraction wereevaluated. The results showed that the chemical crosslinks were the hydroxyl group in citricacid and CMC. Visible UV showed bands associated with the incorporation of CNs. Furthermore, the morphology analysis demonstrated that the CNs were homogeneously spread in the hydrogels. These results showed the great potential of these hydrogels and thepossibility of intensifying the social and economic development of the Brazilian semi-aridregion.

PHB is a biodegradable semi-crystalline polymer and originates from bacterial fermentation of sugar cane. Although PHB has similar mechanical properties to polyolefins such as polypropylene (PP), its widespread application is limited because of its high cost and certain inferior material properties such as brittleness and low impact resistance [1]. Babassu represents natural and cost-effective filler originating naturally from a palm tree found in the North, Northeast and Midwest regions of Brazil. Usually, its shell is discarded and burned without any benefit. In polymer composites babassu yields both, material and technology related improvements as well as economic benefits [2]. In this work, PHB/Babassu biocomposites were processed by compressing molding in the following wt.%:100/0, 90/10, 85/15 and 80/20. The formulations were characterized according to chemical,physical and mechanical properties. Nonlinear regression models were performed to determine the influence of the biocomposite composition on the impact resistance, hardnessand tensile results. The independent variable Babassu content (B) was statistically significant in the evaluated operating range. Tensile testing showed that biocomposite PHB/Babassu 90/10 exhibits mechanical properties similar to PHB, whereas the increase of babassu concentration for 20% wt.% should reduce mechanical properties probably due tothe poor filler-matrix adhesion. The impact resistance of PHB/Babassu was slightly higher inthe 10 wt.% biocomposite, in accordance with Hardness results.

e-mail: rodrigoliscano@yahoo.com.br

In this work, PHB in powder was immersed in distilled water and modified by plasma treatment using a commercial atmospheric-air plasma-jet system [1]. The TPS/PHB formulations were composed of a proportion of 95/5 (%wt). The films obtained were TPS, TPS/PHB, TPS/PHB T40, and TPS/PHB T60. Each formulation was fed into a mono-screw extruder with three temperature zones. The PHB, PHB T40, and PHB T60, in powder, were analyzed through FTIR. All PHB characteristic bands were observed in the modified and unmodified samples. However, changes in the bands around 1720 cm-1 and 1052 cm-1, related, respectively, to C=O and C-O linkage, were observed. The intensity of the bands related to C=O increased with the treatment time. Bands associated with C-O were shifted to lower wavelengths indicating, probably, a change in PHB chains. The PHB characteristics bands were not observed in TPS/PHB T40 and TPS/PHB T60; it indicated that PHB-T´s were encapsulated by TPS. The water absorption analysis revealed that the amount of water absorbed per gram of TPS in the sample decreased with the PHB addition in treated samples. The amount of water absorbed by TPS/PHB T60 was lesser than that observed for TPS/PHB T40, indicating that the interaction between TPS and PHBT changed the TPS absorption behavior. These results corroborated FTIR analysis of TPS/PHB T, where the TPS bands initially at 3304 cm-1 (related to OH group) were shifted for 3268 cm-1 and 3289 cm-1 in the samples TPS/PHB T40 and TPS/PHB T60, respectively. The dimensional analysis of samples was performed. It was observed that PHB improved the dimensional sample''s stability. In conclusion, PHB treated by atmospheric air plasma improved the TPS hydrophilicity and the dimensional stability of composites. Acknowledgements:Faperj. References:[1] V.S. Rosa, T.S. e-mail: nilsonbraitneto@gmail.com

The present study investigated the formation of hybridly reinforced composites simultaneously with the synthesis of biomass-based polyurethane (PU) matrices. Microcrystalline cellulose (MCC) was used as polyol and reinforcement. Castor oil (CO) was used as an additional polyol and also to help disperse the solids reagents. The reactions were carried out with no solvent or catalyst. The isocyanate used was diphenylmethane diisocyanate. The reinforcements were sisal mats and/or short curauá fibers (3 cm long, randomly distributed), with the presence or not of MCC as an additional reinforcement. The materials were characterized by thermogravimetric (TGA) and dynamic mechanical (DMA) analyses, flexural tests, and scanning electron microscopy (SEM). The TGA analysis indicated thermal stability of all materials up to 250°C. The DMA tan delta curves showed glass transition (Tg) below room temperature, approximately 20°C and 2°C for the - unreinforced PU and composites, respectively. The flexural tests carried out at room temperature (about 25 °C) proved elastomeric characteristics for the unreinforced polyurethane and composites without curauá fibers as reinforcement. The SEM images showed good interaction at the interface matrix-fibers and homogeneous dispersity of the MCC used as reinforcement. The materials were prepared from a highly renewable content, inside the circular bioeconomy context, with potential application in various sectors, such as automotive, aeronautical, and nautical industries.

Production and characterization of chitosan particles incorporated with Essential Oil of Oregano for active packaging

Mariana Moraes Góes[1], Vinicius Augusto de Melo Gomes[1], Paula Paulino Silva[1], Juliano Brisola[1], Gizilene Maria de Carvalho[1]

[1]Universidade Estadual de Londrina

e-mail: marianagoes94@gmail.com

Essential oils are substances that can be used in active packaging with great consumer acceptance. However, for its use in industrial packaging production processes, it is necessary to provide for the protection of volatile compounds against evaporation, oxidation, thermal degradation and odor reduction [1]. In this work, chitosan particles were produced by ionic gelling, using sodium trimetaphosphate and sodium tripolyphosphate crosslinkers, with different proportions of essential oil of oregano (OEO) with the objective of evaluating its potential for use in active packaging [2]. FTIR and swelling analyzes confirmed the crosslinking of chitosan and indicated that swelling is influenced by the type of crosslinker and the way in which these substances interact with chitosan. Thermogravimetric analysis demonstrated that particles with encapsulated oil have greater thermal stability than pure oil, serving as thermal protection for the active substance. By Dynamic Light Scattering it was verified that the particles produced with sodium tripolyphosphate have smaller sizes, which influenced the release of oregano essential oil. For the different particles, the oil release is described by a quasi-Fickian release mechanism. The results showed that the produced particles have sufficient thermal stability to be used in the extrusion process up to a temperature of 120 °C, protecting the active substance, in addition to masking the strong odor of the OEO, making them suitable for use in active packaging.

The use of superabsorbent hydrogels in agricultural applications contributes to sustainable development, as they can act as soil conditioners, storing greater volumes of water and reducing the waste that occurs with continuous irrigation [1]. In this way, superabsorbent hydrogels based on polyacrylamide, laponite and cashew tree gum in different concentrations were produced to investigate the swelling capacity and the rheological properties of the hydrogels. The results show normal modes that confirmed the formation of hydrogels by FTIR and that laponite is present in the crystalline network of the nanocomposites by XRD. The presence of laponite in the hydrogels increased the strength of the material based on rheological tests. With the swelling test, it was verified that the increase in pH from 4 to 7 favored the swelling of the hydrogels, however, the swelling capacity decreases with increasing amount of laponite, as the addition of an inorganic filler in the hydrogel matrix causes an increase in crosslink density, resulting in decreased water absorption [2]. In the toxicity test, it was possible to verify low mortality of *Artemia salina* nauplii in both nanocomposite hydrogels, and that materials with higher concentration of cashew gum did not show mortality in the bioassay. The results indicate that superabsorbent nanocomposite hydrogels with higher cashew tree gum content are ideal for agricultural production.

The babassu mesocarp, obtained from the babassu palm (Orbignya sp.) has been gaining notoriety among the Brazilian resource biodiversity due to its high concentration of starch (66 %) which confers functional properties and attractive environment for chemical modifications, being a promising material in biomedical areas [1,2,3]. The objective of this work was to obtain and characterize three oxidized derivatives from babassu mesocarp. The babassu mesocarp was isolated by maceration in an aqueous medium. For the modification of the mesocarp starch, sodium periodate was used in different starch/periodate ratios (m/v). The derivatives obtained were characterized by Fourier Transform Infrared (FTIR), Elementary analysis (EA), X-ray diffraction (XRD), thermal analysis, zeta potential, scanning electron microscopy (SEM), and solubility. In the FTIR spectra, changes were observed in the regions close to 1050 and 1120 cm−1 in the spectra of all obtained modifieds, which are related to primary alcohol groups of the oxidation process. No abrupt changes in the carbon/hydrogen ratio were observed as no new functional groups were introduced; the presence of -OH groups decreased the zeta potential. The XRD analysis evidenced different crystalline patterns among the modifieds, which may be related to the degree of oxidation, corroborating with SEM micrographs. Similar decomposition profiles were observed for all materials and heating-dependent solubility. Thus, the characterizations carried out confirmed the chemical modifications of new biomaterials obtained from babassu mesocarp with potential application in biomedical fields. The use of residues from the agro-industrial process has been a major focus of research in recent years due to the great potential of using residual biomass not only for energy generation, but also for the extraction of compounds that can be used for higher added value purposes, such as extractives, polyphenolic compounds, among others. [1]

Parallel to this, ZnS is a semiconductor material with a series of applications in several fields, such as photocatalysis, solar cells and optoelectronic devices, it is also worth mentioning its thermal properties, due to its thermal conductivity and specific heat capacity. [two]

In this present work, it is intended to obtain nanocellulose from the husk of Pinus elliotti, through a sequence of treatments, aiming to remove the extractives through extraction in water, the lignin through an alkaline hydrolysis, in addition to the bleaching of the pulp, viaa route with chlorides. Finally, the obtained pulp is mechanically defibrillated resulting in a nanocellulose gel. The obtained FTIR spectra confirmed that the treatments were effective in their objective of removing the unwanted phases.

ZnS was obtained through a microwave-assisted hydrothermal synthesis, where the zinc and sulfur precursors were subjected to a reaction at 150°C for 25 minutes, obtaining a white precipitate at the end of the solution, where it was possible to confirm the particle in the order of 200nm by scanning electron microscopy (SEM) and the desired phase by x-ray diffraction (XRD).

At the present moment, samples of the nanocomposites are being obtained through hydrothermal synthesis with ZnS precursors and nanocellulose in different ratios.

Synthesis of films based on chitosan and protic ionic liquids to be used as wound dressing films for oral mucosa

Leonardo Ferreira Medeiros[1], Roberta da Silva Bussamara[1], Luiza Abrahão Frank[1], Silvia S. Guterres[1], Lina Hashizume[1], Fernanda Visioli[1], Adriana Raffin Pohlmann[1], Sandra Cerqueira Pereira[2]

[1]Universidade Federal do Rio Grande do Sul, [2]Universidade Federal da Bahia

e-mail: leonardo.ferreira@ufrgs.br

The oral mucosa is important in protecting against pathogens. Various lesions can occur due to various causes, including traumatic injuries and neoplasms. These wounds can lead to systemic infections, aggravating the risks. Usually, ointments are used as a protective barrier, but they have a short duration. Films with mucoadhesive and antimicrobial properties are a great alternative to ointments because they provide a barrier against pathogens, avoid infections, and facilitate rapid and better healing of injuries by prolonging contact with the mucosa [1]. Among the materials used for making a film, chitosan has shown high potential for biocompatibility and biodegradability, but with low elasticity. Therefore, the use of plasticizers, such as ionic liquids (ILs) is necessary [2]. The films were developed by dissolving chitosan in acetic acid, in the presence of ILs: 2-hydroxydiethanolamine lactate (DLa), salicylate (DSa), and maleate (DMa). The proportions of ILs tested in relation to the mass of chitosan were 10%, 35%, and 50%. The solutions were stirred for 3 hours at room temperature. The samples were characterized by swelling degree (SD), mechanical analysis, antimicrobial properties, mucoadhesion, and cytotoxicity. The SD was inversely proportional to the amount of IL added. The mechanical analysis showed a significant change in the films when ILs were added. Antimicrobial activity was only found in films containing the IL DSa at all analyzed concentrations, and they also showed higher mucoadhesion compared to the others. Regarding cytotoxicity, the films in general did not presented cellular damage and cell growth was observed. Due to better homogeneity, elasticity, antimicrobial activity, and mucoadhesion, the chitosan-based film with DSa IL appears as a promising material for use in the treatment of oral mucosa diseases.

e-mail: sidney.souza@unesp.br

Nanoparticles, especially formed by noble metals, are used in various industrial and pharmaceutical applications. Among these metals, silver has attracted attention mainly due to its high affinity and adhesion to the cell membranes of biological systems1. The biological route of nanoparticle production has advantages over the conventional chemical route, because the usual methodologies require not only a reducing species of metal ions in solution, but also stabilizing agents of the nanoparticles created that aims to avoid their coalescence and phase separation2. The present study investigated the formation of silver nanoparticles (AgNPs) through synthesis mediated by aqueous extracts of orange peel (Citrus sinensis) under different conditions, evaluating the impact of the variation of experimental conditions (plant extract concentration, pH and temperature) in obtaining the dispersions of the nanostructures. After the production of the aqueous extract of the orange peel (20 g of pulp in 40 mL of water) three dilution conditions were investigated (1:1; 1:2 and 1:4). It was found that low concentrations (1:4) in the reaction medium were not sufficient to reduce all silver ions present during the time period investigated. In parallel, high concentrations of phytochemicals (1:1) generated a possible competition of silver cations. The conditions in alkaline medium exhibited bands related to the formation of AgNPs at shorter wavelengths, according to the UV-VIS spectroscopic technique, indicatingthe occurrence of smaller and more uniform nanostructures with respect to acidic media. The DLS results also exhibited a similar trend, indicating a lower mean of AgNPs in alkalinemedium compared to samples obtained in acidic media. For the temperature variation, withthe increase of the same there was an intensification of the signal of the surface plasmo resonance band (RPS).

Tunning the chemical and electrochemical propertiesof carbon paper-based electrodes by pyrolysis of polydopamine nanofilms

e-mail: jaqueline.falchi@lnnano.cnpem.br

Electrochemical paper-based analytical devices are very promising toward high-sensitivity, low-cost, affordable, miniaturized, user-friendly and decentralized analysis for applications in the health field. Regarding such properties, chemical functionalization plays a pivotal role to tune sensitivity, selectivity, and surface area of electrodes (1). However, it is challenging to control different surface properties using a single functionalization route. In this work, we attempted to tune the wettability, chemical composition, and electroactive area of carbon paper-based devices by thermally treating polydopamine at different temperatures. Polydopamine (PDA) nanofilms (2) were first deposited on pyrolyzed paper electrodes and thermally treated in the range of 300 - 1000oC in a second step. After deposition of PDA, the surface is rich in nitrogen and oxygen, hydrophilic and with a high electroactive area. As the temperature increases, the surface becomes hydrophobic and the electroactive area decreases. The surface modifications were followed by Raman, XPS, laser scanning confocal microscopy, contact angle, MEV-EDS and electrochemical experiments. In addition, different chemical compositions of nitrogen species can be tuned on the surface. As a proof-of-concept, we employed the PDA treated surfaces to anchor AuCl4- ions. After electrochemical reduction, we observed that depending on the temperature used it is possible to control the size of the nanoparticles on the surface. Our route opens a new avenue to add versatility to electrochemical interfaces.AcknowledgmentsThis work was supported by LNNano, SISNano, CNPEM, UFABC and CAPES. References:1. Q-Materials for Additive Manufacturing

Additive manufacturing of ceramics, opportunities and challenges with emphasis on vat polymerization

Carlos Alberto Fortulan[1]

[1]Escola de Engenharia de São Carlos (USP) (*Engenharia Mecânica*)

e-mail: fortulan@usp.br

Additive manufacturing (AM) of ceramics is a reality in the production of complex, customized, and high-performance parts. Almost all additive manufacturing techniques have been tried for ceramic materials. The selection of a technique depends on the compromise between parameters and the required properties of the product. For products with high mechanical performance, precise shape and, the vat photopolymerization (VP) process by Digital Light Processing (DLP), an indirect method, has reached high levels of acceptance worldwide. It has the following key requirements: 1) formulation of a photocurable slurry with high ceramic solid loading (~50 vol%); 2) equipment that adds uniform layers of slurry and projects on its surface an image with a light spectrum of interest, polymerizing slice by slice of the part; 3) debinding with a controlled removal of the organic fraction; 4) distortion-free sintering. This work presents characteristics of the leading ceramic additive manufacturing techniques with their main advantages and challenges, emphasizing the importance of research in the early days of this recent manufacturing area.

Additive manufacturing of PLA/SEP bionanocomposites: Influence of nanoparticle content and printing conditions on crystallinity and morphology

Yan Faria Guimarães Silva[1], Juliano Marini[1]

[1]Univerdade Federal de São Carlos (*DEMa*) *e-mail: yanfgs@gmail.com*

Fused Filament Fabrication (FFF) process is widely used as additive manufacturing (AM) technology. One of the most important challenges faced by the FFF technique is the development of new raw materials and the definition of their processing conditions [1]. There is great interest in the development of PLA (poly(lactic acid))-based materials for 3D printing mainly due to its excellent properties such as biocompatibility, biodegradability, processability and mechanical performance [2]. Crystallinity in polymeric materials is a fundamental factor to understand their performance during application, as well as their dimensional stability and shrinkage during and after forming. The crystallization of PLA depends on the type of stereoisomer used in its synthesis, the presence of additives in its formulation, as well as the conditions employed during its conformation process [3]. In this work, PLA bionanocomposite filaments with different contents of sepiolite nanoparticles (SEP) were developed through twin-screw extrusion, with subsequent conformation of specimens by FFF at different times of exposure to the thermal environment typical of the process, evaluating the variation of the degree of crystallinity in different regions of the specimens and the morphology of the printed parts. The results indicate that, for the PLA used, the crystallinity is more dependent on factors related to the composition (presence and content of SEP) than to the printing conditions analyzed. The presence and content of SEP also had a significant influence on the printability of the materials, since the higher the content, the more reproducible the process and the better the adhesion of the deposited layers.

Holistic approach for quality assurance and quality control for laser powder bed fusion

Edson Costa Santos[1]

[1]Carl Zeiss Industrielle Messtechnik GmbH

e-mail: edson1.costa-santos@zeiss.com

The fact that additive manufacturing (AM) produces the structural material and the shape of the manufactured object together, is the very basis for the huge design freedom and at the same time the reason for a fundamental quality control challenge: Historically, quality assurance and control (QA/QC) is done separately for (i) the material composition and integrity (e.g. light microscopy, EBSD, …), (ii) surface inspection (e.g. by microscopy, deflectometry, …) and (iii) form measurement (e.g. fringe projection, laser scanner, …). Additive manufacturing produces errors in all three categories: Defects like voids and cracks in the material, rough surfaces from layerwise production and form errors e.g. due to stress. In consequence any single measurement method is insufficient for characterization. Even CT, the current gold standard, is limited as a single method because of lack of penetration of high density materials and limited resolution. So, we need a multi-method approach with a correlation of the individual results. In this presentation, we will explain how in process monitoring can be used to identify anomalies and variations during laser powder bed fusion and apply CT based solutions to link process stability and part integrity. ZEISS, as a provider of metrology and inspection equipment of a broad variety, is collaborating with industrial partners to exploit this potential.

Mechanical properties of an aluminum quasicrystal-forming alloy prepared by laser powder bed fusion

Piter Gargarella[1], Aylanna Priscila Marques de Araújo[1,2], Claudio S. Kiminami[1], Volker Uhlenwinkel[3]

[1]Univerdade Federal de São Carlos, [2]Programa de pós-graduação em Ciência e Engenhariade Materiais, [3]Leibniz-Institut für Werkstofforientierte Technologien - IWT

e-mail: piter@ufscar.br

Al-Fe-Cr-Ti quasicrystalline phase former alloys are metastable materials that form a quasicrystalline phase (QC) in an α-Al matrix. The combination of the high-strength QC phase in a ductile α-Al matrix gives rise to composites with good mechanical properties inhigh temperatures. High cooling rates are needed to precipitate the QC phase, which turnsthe processing of these alloys into a challenge. The purpose of this work was to use the Laser Powder Bed Fusion (LPBF) process, which applies cooling rates around 104 K/s, to fabricate Al95Fe2Cr2Ti1 samples using gas-atomized powders produced from recycled material. The room and high-temperature (up to 500°C) tensile properties and microstructure of the LPBFed Al-Fe-Cr-Ti alloy were investigated. The LPBF led to a microstructure with nm-d quasicrystalline precipitates in a dendritic α-Al matrix. The QC phases were present mainly in the center of the molten pool, while the heat-affected zones showed coarser but also nanometric quasicrystalline and crystalline phases. The samples exhibit high thermal stability and outstanding mechanical performance with yield strength values of ~300 MPa and ~180 MPa at 300°C and 400°C, respectively. A model is proposedto predict the yield strength of the alloy, showing good agreement with the experimental results. The crack propagation mechanism was investigated, and a considerable influence of the build direction in the ductility at room temperature was observed. The results obtained show a new opportunity to fabricate metastable quasicrystal forming alloys for high-temperature applications with freedom of design and lower cost.

Microstructure of a heat-treated 420S SS deposited by LDED on AISI D2 substrate

Moysés Leite de Lima[1], Giovanna Fiocco Colombo[2], Jeferson Trevisan Pacheco[3], Marcelo Taveira Veiga[3]

[1]Instituto de Pesquisas Tecnológicas (*Laboratório de processos metalúrgicos*) , [2]Instituto de Pesquisas Tecnológicas, [3]Instituto Senai de Inovação em Processamento a Laser

e-mail: mllima@ipt.br

Laser Directed Energy Deposition is one of the processes most used for metallic materials additive manufacturing. It also can be used for coatings deposition, in which it is possible to deposit a different material of the substrate. The understanding of the microstructure formation and its evolution during the processes chain, including post-processes steps, are of fundamental importance in the development of applications of this process. The present work presents a microstructure characterization of a 420S steel deposited by LDED on an AISI D2. In addition to the as-deposited microstructure, the effects of distinct heat treatment routes on the microstructure evolution of 420S steel were evaluated. These heat treatment cycles were tempering at 300 °C, 400 °C, and 500 °C with and without the quenching step. The microstructures were analyzed by optical microscopy, scanning electronic microscopy, and microhardness measurements. The as-deposited 420S steel microstructure is predominantly made up of austenite and martensite. Tempering heat treatments directly from the as-deposited condition did not result in significant microstructure changes. However, it was possible to observe changes in the microhardness field consistent with what was expected for the tempered martensite of 420S steel. Moreover, the tempering treatments did not reduce the microhardness heterogeneities of the as-deposited material. The quenching heat treatment significantly changed the microstructure of the deposited material, probably due to recrystallization in the austenitization step, during which there was possibly carbon transport by diffusion from the AISI D2 steel to the 420S SS. This carbon transport was probably responsible for a microhardness profile formation, avoiding a step transition between the materials. The quenching and tempering heat treatments resulted in microstructures consisting predominantly of tempered martensite, as expected for 420S steel.

Selective Laser Melting of β Ti Micrometric Powdersdown to Atomic Sputtering of Thin Films for Implant Applications

Conrado Ramos Moreira Afonso[1], Felype Narciso de Mattos[2], Pedro Augusto de Paula Nascente[3], Rubens Caram[4]

[1]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais (DEMa)*) , [2]Univerdade Federal de São Carlos (*Graduation Program in Materials Science and Engineering (PPGCEM)*) , [3]Univerdade Federal de São Carlos (*Department of Materials Engineering (DEMa)*) , [4]Universidade Estadual de Campinas (*Mechanical Engineering Faculty (FEM)*)

e-mail: conrado@ufscar.br

β Ti alloys are acclaimed for biomedical applications due to their mechanical properties, good biocompatibility and corrosion resistance. Based on these characteristics, pure Ti and different Ti alloys have been applied in the biomedical industry, especially the Ti-6Al-4V alloy. However, for orthopedic applications, there is a considerable difference between elastic modulus of Ti and α+β alloys, from E = 100 to 110 GPa, and that of human bone,around E = 30 GPa. Another approach is produce a coating (~1 μm thin film) over a highermodulus alloy (stainless steel - SS) in order to reduce the surface elastic modulus of SSimplant adopting low modulus β Ti-Nb-based alloy thin films. In this context, the metastableβ alloy Ti-15Nb (% by weight) was processed by selective laser melting (SLM) and arcmelting, since this is free of cytotoxic elements and shows lower Young modulus. Characterization of SLM β Ti-15Nb alloy and Thin Films of β Ti-Nb-based alloys obtained bymagnetron sputtering were done by optical microscopy (OM), X-ray diffraction (XRD), scanning electron microscopy (SEM) and transmission (TEM) coupled to ASTAR - automaticcrystal orientation mapping (ACOM). Vickers microhardness, and elastic modulus via nanohardness and impulse excitation were evaluated. The coating of Ti40Nb20Zr40 alloy(at.%) presented lower elastic modulus of 51 GPa and hardness values, and these wererelated to the increases in both the lattice parameter and mean nanoscale grain size of thinfilm. For SLM of β Ti-15Nb alloy with a α´+ β microstructure, the Vickers microhardnessand elastic modulus measured by nanohardness and impulse excitation technique were evaluated, showing suitable modulus of around 60 GPa for biomedical applications. Besidesthat, the microhardness was found around 300 HV and density, which plays an importantrule in mechanical properties, was found above 99%. Therefore, SLM of β Ti-15Nb has beenshowing a promising material for orthopedic applications.

Additive manufacturing of microstructures with nanometric resolution

Izaque Alves Maia[1], José Luis D'avila Sánchez[2], Juliana Kelmy Macario Barboza Daguano[2], Juliana Girón Bastidas[2], Claudio Yamamoto Morassuti[2], Gustavo Henrique de Magalhães Gomes[2], Pedro Yoshito Noritomi[2], Jorge Vicente Lopes da Silva[2]

[1]Centro de Tecnologia da Informação Renato Archer (*DITPS*) , [2]Centro de Tecnologia da Informação Renato Archer

e-mail: izaque.maia@cti.gov.br

Additive manufacturing using the Two-Photon-Polymerization (2PP) technique can produce microstructures with nanometric resolution. The 2PP process involves using a femtosecond laser with a focal point of either 780 nm or 522 nm to activate a photopolymerization agent. This technique has various applications in fields such as micro-optics, micromechanics, microfluidics, biomedical engineering (including biofabrication and medical instruments), surface texturing, filters, and metamaterials. Additionally, microstructures can be built integratively on pre-existing structures, such as fiber optic tips and optoelectronic/microfluidic circuits. 3D printers capable of this integrative resource are already being commercialized. CTI Renato Archer is acquiring an I3D/2PP printer through the EMUTISAÚDE Project (FINEP 01.18.0027.00). This printer has several specific features, including the ability to use photosensitive hydrogel-based bioinks that can incorporate living cells. Furthermore, it does not use the dip-in technique, which can compromise lens durability and facilitates the development of custom photopolymers. The printer uses an adaptive voxel size that can build regions of different resolutions in the same structure, and its configuration can be upgraded to print mesoscale structures in conjunction with micro-ones. The I3D/2PP printer will be made available to Brazilian researchers by the Coordination of Technological Park and Open Laboratories (COLAB) of CTI Renato Archer by the end of 2023. This work will detail the principles of operation, types of photopolymers, and applications of I3D/2PP, aiming to encourage researchers to submit project proposals to COLAB.Acknowledgements:FINEP and CNPq - Brazilian financial research agencies

A review of the modification of aluminum powders for processing by LPBF

Nicolas Rojas Arias[1,2], Francisco Gil Coury[3], Sergio de Traglia Amancio-Filho[1], Piter Gargarella[4,5]

[1]Graz University of Technology (*IMAT*) , [2]Federal University of Sao Carlos (*PPGCEM / DeMa*) , [3]Univerdade Federal de São Carlos (*Engenharia de Materiais*) , [4]Univerdade Federal de São Carlos (*Department of Materials Engineering*) , [5]Federal University of Sao Carlos (*Materials Engineering*)

e-mail: nicolas.rojas@estudante.ufscar.br

The aluminum alloy processing in laser powder bed fusion (LPBF) is constantly limited due to the raw material`s intrinsic characteristics that hinder the alloy processability within this process. Although casting aluminum alloys with an Al-Si(Mg) base composition, are usually easily processable within LPBF, these alloys present a low mechanical performance. In contrast, wrought aluminum alloys are characterized by optimal mechanical properties which can be optimized by applying heat treatments. Nevertheless, its wide solidification interval increases its hot-cracking susceptibility (HCS). Likewise, aluminum powders are characterized by their high reflectivity, which requires high energy inputs to guarantee the melting of the powder bed, which difficult their application by LPBF. These limitations can, to a large extent, be mitigated by modifying the raw material from the incorporation of reinforcing particles, the adaptation of the alloy composition, and the surface modification of the powder particles. Considering the above, this review contains the different strategies used to modify and design aluminum alloys suitable to LPBF, related to: 1) inoculation and reinforcing by adding ceramics and intermetallic composites, 2) Reduction of the solidification interval, and 3) surface modification, as well as their effect on the mechanical properties and improvements in the printability of aluminum alloys by LPBF. Likewise, some of the technological contributions that have facilitated the modification and design of aluminum alloys for the LPBF shall be mentioned. The compilations made in this review shall allow visualizing the recent technological advances in the area and the discussion of key issues that require attention to continue advancing within this work-line.

Computational modeling of the mechanical behavior of additively manufactured PA12.

e-mail: joan.oconnor@int.gov.br

.Additive Manufacturing (AM) opposite from conventional subtractive processes, consists in make parts or components from a 3D model data by joining materials layer by layer. This fabrication method has gained a lot of attention and is continuing to grow and deliver critical and complex parts and components in multiple industry sectors, according to intelligence market ASTM Wholers. This technology offers several advantages comparatively to conventionally subtractive manufacturing methods, however, the understanding of the behavior of components manufactured using AM is much lower compared to that of conventionally manufactured materials, presenting additional challenges to perform more accurate analyzes. Therefore, and particularly for polymer materials, the objective of the present work is the study the mechanical behavior of the Polyamide PA12 additively manufactured using Selective Laser Sintering (SLS), submitted to uniaxial tension, through experimental testing and numerical simulations. For this purpose, a comparison of the stress-strain behavior of a standard specimen for tensile tests and a complex geometrical specimen was carried out. In addition, computational simulations using the finite element method (FEM) were performed in COMSOL Multiphysics 5.6, using a viscoplastic Chaboche constitutive model, for the characterization of the mechanical behavior of the PA12 specimens under uniaxial tensile and the corresponding experimental validation [1-3]. The results have shown excellent agreement of the implemented FEM model with the experimental test, for both cases, the standard and the complex geometrical specimens, considering a time-dependent load environment, and the methodology could be extended to other polymer materials. Acknowledgments: The authors would like to thank CNPq for the financial support of this study. References:[1] de Souza Neto, E., Peric, D., Owen, D., 2011. e-mail: juliane.rcruz@gmail.com

Corrosion resistance is a critical requirement for materials used in a range of applications, where exposure to harsh environments can cause degradation or failure induced by high concentrations of moisture, oxygen and other chemical elements. Thus, the development of corrosion resistant materials and suitable processing techniques, to ensure durability and reliability of components in these industries is essential. This study investigates the corrosion resistance of AlSi10Mg alloys produced by Laser Powder Bed Fusion (L-PBF) and benchmarks it against the conventionally processed casted AlSi10Mg and extruded heat-treated Al 6061 T6. Cyclic polarization tests in NaCl 3.5% naturally aerated media were used to assess the corrosion resistance of specimens, tested in duplicate and in the as-polished condition. The microstructure and corrosion mechanism were investigated by optical microscopy and the chemical composition by optical emission spark. Results show that the casted AlSi10Mg and the Al 6061 T6 specimens had very similar behavior, showing a steep increase in current density after the onset of corrosion and no signs of passivation. On the other hand, L-PBFed AlSi10Mg specimens developed a more noble corrosion potential with corrosion rates at least 20× smaller than those of the samples processed byconventional techniques. Besides, these samples were also able to passivate in aggressive media, developing much smaller corrosion rates throughout the test. The superior corrosion resistance of the specimens processed by L-PBF seems to be associated to a higher purity and to the fine-grained microstructure that accounts for the formation of a denser passive layer. Overall, this study demonstrates the promising potential of advanced manufacturing techniques for producing corrosion-resistant components, with important implications for industry.

Cracking susceptibility of AISI A2 Tool Steel manufactured through Laser Powder Bed Fusion

Bruno Bianchini[1], Piter Gargarella[2,3], Leonardo do Carmo Braghim[1]

e-mail: brunobcn294@gmail.com

Tool steels are materials used for the fabrication of tools employed in the manufacturing processes of other materials (i.e. cutting, shaping, forming) and, depending on their use, require specific mechanical properties to be enhanced. These range from resistance to softening at high temperatures, to wear resistance or strength and toughness, these last two being the most important for cold-work tool steel grades [1]. Given the strict requirements for manufacturing and heat treatment of tool steels and the higher difficulty to machine complex structures into them, Additive Manufacturing (AM) through Laser Powder Bed Fusion (L-PBF) could be an alternative to conventional manufacturing methods. However, in the case of high carbon content materials, such as high-speed or cold-work tool steels, the severe cooling rates and steep thermal gradients imposed by L-PBF cause high thermal stresses to appear, which may in turn cause these materials to experience cracking [2]. In this sense, solutions have been researched in order to prevent these defects from appearing, such as baseplate preheating to reduce thermal gradients [3], or the use of different scanning strategies, in order to better distribute stresses. In this work, cracking behavior of Tool Steel AISI A2 manufactured through L-PBF was investigated by optical microscopy, for unheated and preheated baseplate at 200°C and 500°C. Microstructure was also investigated by SEM analysis and phase composition was determined by Rietveld analysis of synchrotron XRD results, for as-built samples and tempered at two different temperatures (200°C and 500°C).

In structural materials, mechanical behavior improvements always focus on increasing mechanical strength, ductility, and toughness; however, these properties are mutually exclusive. Generally, the enhancements in strength occur at the expense of ductility and vice versa in the context of the strength-ductility paradox. An approach to enhance ductility (and toughness), while preserving mechanical strength, is to merge different materials to produce a composite material arrangement. Additive manufacturing (AM) technology is an effective approach for fabricating metallic composite materials with enhanced mechanical strength and ductility. Laser powder bed fusion (L-PBF), also known as selective laser melting (SLM), is an AM technique that enables the manufacture of customized objects. The concept of AM, which involves constructing objects by depositing layers of powder with the ability to vary their composition, is particularly well-suited for manufacturing composite materials or compositionally graded materials. Currently, multi-material processing represents a crucial challenge in the additive manufacturing of metallic materials. This study aims to provide new insights into the manufacturing of composite materials made up of alternating layers of different Ti-based materials (CP Ti / Ti-6Al-4V alloy and Ti-42Nb /Ti-5553 alloys) using a novel multi-material laser powder bed fusion platform. Very dense layers were obtained. The evaluation of the interface between the two materials indicated intense atomic diffusion. The Vickers hardness and elastic modulus tests revealed that the values varied according to the phase and composition. The results revealed the successful production of composite materials.

e-mail: daniela.fonseca@sc.senai.br

Maraging 300 (M300) is an high strength steel that has shown excellent response to L-PBF (Laser Powder Bed Fusion) due to its good processability, machinability and dimensional stability [1]. L-PBF processing combined with the properties of M300 is promising for the studies of cooling channels [2]. Efficient cooling channels should provide uniform cooling and reduce cooling time [3]. This work aimed to develop L-PBF parameters for the fabrication of cooling channels by varying contour parameters and channel profiles. To investigate the optimal contour parameters, octagonal prims were produced by L-PBF with three scanning strategies (bulk without contour, bulk before contour, contour before bulk), three contour power (100, 125 and 150 W) and three contour scanning speeds (400, 450 and 500 mm/s). Ten different cooling channel profiles were fabricated, varying the channel cross-sectional area and geometry (circular, semicircle and conformal). Optical microscopy (OM) and scanning electron microscopy (SEM) were used to assess the channel dimensions and surface conditions, the images were analyzed in specialized software to obtain the roughness, density and porosity. Results showed that M300 can be processed by L-PBF with high density (up to 99.98 %) and surface roughness can be reduced (Ra ≈ 8 μm) without increasing contour porosity. The optimal contour parameter was obtained by scanning bulk before contour with laser power of 125 W and scanning speed of 500 mm/s. Channels manufactured with the optimized contour parameter showed better dimension control and fit to the digital project, than channels produced without the contour scan. Results also indicated that the channels with a conformal geometry showed good surface conditions and a cross-section area that could favor the coolant flow.

The ever-growing orthopedic implants market is a result of the increased life expectancy. In this regard, the demand for implants with better functionality and longer lifespan also grows, creating a constant need for research in new materials and processes for orthopedical implants. One of the main causes of implant failure is aseptic loosening, caused by a mismatch between the stiffness of the bone and the material of the implant. Metallic materials are currently the most used materials in orthopedics, but even biocompatible alloys with low Young modulus still have properties far beyond the ideal. In this regard, porous materials can be a feasible alternative as they present lower stiffness when compared to solid bulk materials. Additive manufacturing allows the production of porous materials and a precise control of the pores morphology, , and interconnectivity, which are vital features to control both mechanical properties and biological response. However, these structures are complex and their behavior as an implant material is not fully understood. The human body is a dynamic and complex environment, and an orthopedic implant material is commonly subjected to various aggressive conditions, such as corrosion, wear, fatigue, and high mechanical loadings. This work produced Ti-6Al-4V porous lattice structures and solid bulk samples using electron beam melting (PBF-EB) additive manufacturing process and compared their behavior under wear and tribocorrosion tests. All the porous and bulk solid samples presented similar behaviors under wear and tribocorrosion, with no statical differences between the specific wear rates. Abrasive and adhesive wear were the dominant mechanisms of material removal. In conclusion, the presence of pores did not increase the specific wear rates of the material, but, as a effect of the porosity, a lifespan reduction under wear and tribocorrosion conditions is expected for the porous material.

EXPERIMENTAL ANALYSIS OF PARAMETERS FOR USE OF AISI H13 IN ADDITIVE MANUFACTURING PROCESS – LASER POWDER-DIRECTED ENERGY DEPOSITION

Additive manufacturing (AM) of metals is a disruptive technology in Industry 4.0 that enables the creation of complex 3D geometries from computer-aided design (CAD). AM has been widely adopted in various industries, including aerospace, energy, and mold repair and manufacturing. Directed energy deposition (DED) is one of the AM technologies, which uses a laser beam or an electron beam to fuse powder metal or wire onto a substrate or a manufactured part. Beads are deposited on top of each other to create layers and form the desired geometry. However, due to the characteristics process, there are defects such as porosity, and lack of fusion between the layers, which can be caused by overlapping, distance between the beads, deposition strategy and loss of the laser focal point in this research, it was carried out an experimental analysis of these variables process parameters such as laser power, mas. s-volumetric flow, and scan speed. using AISI H13, one of the most common materials used in mold repair and fabrication. The samples were characterized using confocal laser microscopy, scanning electron microscopy (SEM) and, Vickers microhardness. The results show that high mass or volumetric flow rates induce porosity and lack of fusion in the depositions. The scan speed, overlapping and laser power affect the layer's dimensions, generating problems throughout the material deposition. Furthermore, it was found that the manufacturing parameters do not influence the microhardness of the component.

Exploring the Use of HDDR-Processed Powders as Feedstock for Powder Bed Fusion Additive Manufacturing of Bonded Magnets

Rare earth permanent magnets are crucial components in various high-tech applications, such as electric motors, wind turbines, and hard disk drives. However, these magnets are typically expensive and their production relies on rare earth metals and their alloys, which are often limited in availability [1]. To address this issue, the use of hydrogenation disproportionation desorption recombination (HDDR) has gained popularity as a method to recycle and recover rare earth metals [2]. This process can produce high-quality rare earth powders from scrap magnets or other waste sources, which can then be used as feedstock for the production of bonded magnets. Additive manufacturing (AM) is a promising technology for the production of rare earth bonded magnets, with powder bed fusion beinga popular technique due to its design flexibility and material waste reduction [3]. However,the success of powder bed fusion in producing rare earth bonded magnets depends heavilyon the quality and properties of the feedstock powders used. This work explores the use ofHDDR-processed rare earth powders as feedstock for powder bed fusion additive manufacturing to produce bonded magnets. The effect of HDDR processing parameters on the magnetic properties and microstructure of the feedstock powders is investigated. Finally, the powders are used as feedstock for powder bed fusion AM to produce bonded magnets, and the resulting magnets'' microstructure and magnetic properties are analyzed and compared to those of conventional rare earth bonded magnets. The findings of this study have significant implications for the production of rare earth bonded magnets using powder bed fusion AM. Using HDDR-processed rare earth powders as feedstock could potentially reduce dependency on costly rare earth metals and offer a more environmentally-friendly approach to producing high-performance magnets.

Gas Atomization of AA2017 for Additive Manufacturing:A Systematic Investigation into Powder Production and Processing

Vitor Eduardo Pinotti[1], Angelo F Andreoli[1], Piter Gargarella[1] [1]Univerdade

Federal de São Carlos (*Department of Materials Engineering*) *e-mail:*

vitorpinotti@hotmail.com

Gas atomization (GA) is the main method for producing metallic powders for Laser Powder Bed Fusion (L-PBF) [1,2]. Optimization of GA is crucial to achieve specific particle properties and increase productivity [3]. This study analyzed the influence of three main process parameters (atomization pressure (P); nozzle diameter (D); and superheat temperature (T)) on obtaining AA2017 aluminum alloy powders. One experiment (D=1.5mm; T=150°C; P=20 Bar) produced metallic particles with suitable flowability and density for L-PBF. Results showed that process parameters had poor influence on d50 but significantly affected the width of size distribution curves. A mathematical analysis using the Lubanska equation resulted in a good correlation between measured and calculated d50 ($R2 = 0.97$).

Laser heat treatment of AISI M4 multilayers depositedby L-DED

Gustavo Scheid Prass[1], Beatriz Aparecida Pinto[1], Jeferson Trevisan Pacheco[1], Marcelo Taveira Veiga[1], Giovanna Fiocco Colombo[2], Moysés Leite de Lima[2]

[1]Instituto Senai de Inovação em Processamento a Laser, [2]Instituto de PesquisasTecnológicas

e-mail: gustavo.prass@sc.senai.br

Tool repair performed by Laser Directed Energy Deposition (L-DED) has shown promising results for the tooling industry [1]. L-DED provides the flexibility to repair diverse geometries, considering the multiple tool failure modes and locations. Given that the materials used in the L-DED repair operation must have equal or better performance than the matrix, post-processing heat treatments are frequently required. Localized heat treatments, such as laser heat treatment (LHT), can be performed to avoid the costs of heat-treating the repaired tool in furnaces [2]. In this study, AISI M4 multilayers were deposited by L-DED on AISI D2 plates and the effect of LHT with different parameters was assessed. The LHT was performed with a laser spot of 3 mm x 20 mm, scan speed of 10, 15 and 20 mm/s, and temperature of 1050, 1150 and 1250 ºC. The multilayers deposited and heat-treated were analyzed by optical microscopy, scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS) and microhardness. The cross-section micrographs reveal multilayers with low porosity and no cracks. The mean hardness of the AISI M4 deposited multilayer in the as-deposited condition (675 ± 41.85 HV) and after LHT (770 ± 39.29 HV) was higher than the AISI D2 substrate (595 ± 28.75 HV). Moreover, the results show that LHT can be used in combination with L-DED in the recovery of complex tooling, providing flexibility in repair operations and improving material performance.

e-mail: rafael.gitti@posgrad.ufsc.br

Rare earth-transition metal (RE-TM) based permanent magnets are an important class of functional materials essential to renewable energy and e-mobility applications. Among all other ferromagnetic compounds, the Nd-Fe-B is the most important magnetic system, vital for such applications. Beyond its magnetic properties, permanent magnets based on the Nd-Fe-B can be obtained either as a polymer-matrix composite or in a bulk sintered form [1]. The possibility to combine either magnetic and geometrical features have made Additive Manufacturing (AM) techniques gain momentum and rise as potential route to fabricate functional magnetic components with tailored properties. One key step of permanent magnets manufacturing is the crystallographic texture development, where the magnetic flux is enhanced in one particular direction. Concerning AM of Nd-Fe-B composite magnets, the state-of-art reports two different approaches to realize such step, both using a magnetic torque. The first one is carried out during the AM procedure (in-situ), where the magnetization of the powder bed or a composite filament is realized. The anisotropic particles then are oriented parallel to the external magnetic field inducing magnetic anisotropy. The second method is performed as a post-printing procedure, where the as-printed magnet is heated at elevated temperatures under an external magnetic field, allowing the particles to align towards a particular direction. The complex integration of a magnetic field source into the AM process, limited crystallographic texture and severe geometrical distortions exhibited by the fabricated components are some of the bottlenecks of the reported methods. This work addresses the challenges towards the magnetic texture development routes of RE-based composite magnets obtained via AM. An alternative in-situ technique based on mechanical torque is also discussed.

Main parameters and challenges for producing high-quality alumina-based ceramic parts via digital light processing technique

Jhonata Rafael Verza[1], Ana Paula da Luz[1]

[1]Federal University of Sao Carlos (*Materials Engineering Department*)

e-mail: jrverza@gmail.com

Additive manufacturing techniques based on vat polymerization have been receiving special attention due to their ability to produce complex ceramic parts without the high cost of molds usually required for traditional processing methods [1]. However, the design of optimized photosensitive suspensions as well as the control of the printing parameters can have a major influence on the quality of the resulting ceramic parts [2]. In this context, this work evaluated intrinsic (exposure time and layer thickness) and extrinsic parameters (curing depth, dispersant content, and heat treatments) required for the digital light processing of alumina-based ceramic pieces. Light-curable suspensions with 50 vol.% of reactive alumina and different dispersant contents were formulated and had their rheological and stability behavior analyzed. The suspension with the most promising performance was selected and various ceramic parts were printed in a commercial printer, considering distinct exposure time and layer thickness values. The permanent linear change, bulk and relative densities, mechanical strength, and microstructural features of the samples were evaluated after debinding and sintering steps up to 1550°C. A processingmap (correlating relative density, exposure time, and layer thickness parameters) was designed and analyzed. In general, exposure times greater than 4s led to ceramic parts withhigh relative density (>78%) and suitable performance, whereas shorter time.

Mechanical behavior of additively manufactured maraging steel samples

Pedro Luiz Lima dos Santos[1], Julián Arnaldo Ávila Diaz[2,3], Eduardo Bertoni da Fonseca[4], André Henrique Guimarães Gabriel[4], André Jardini[5], Faculdade de Engenharia Mecânica[6]

[1]University of Leeds, [2]Universidade Estadual Paulista, [3]Universitat Politècnica de Catalunya, [4]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*) , [5]University of Campinas, [6]University of Campinas (*School of Mechanical Engineering*)

e-mail: pedroluizcsc@gmail.com

This study aimed to assess how aging affects the mechanical properties of maraging steel (M300_ processed by additive manufacturing, laser-powder bed fusion technique, and aged in different conditions. Aging heat treatment was carried out at temperatures of 470 °C, 510 °C, and 530 °C, with times ranging from 0.33 to 96 h, followed by air cooling. Despite the layer-by-layer consolidation mechanism of the material, we found a weak preferred orientation in the as-built condition, and X-ray diffraction analysis revealed the presence of only martensite and austenite. After aging, our results showed a sharp increase in Vickers hardness, compressive strength, and tensile strength, while the work-hardening ability of the samples decreased. Despite using thin single-edge bending samples measuring 5 mm, the plane-strain fracture toughness (KIC) requirement was met, and we obtained valid KIC results ranging from 49 to 64 MPa.m$^{1/2}$[1]. These findings have important implications for designing new applications of high-strength steel in additive manufacturing, including thin-walled, lattice structures, and reduced cross-section parts aimed at minimizing weight across different industries.

Mechanical Properties of 410L Stainless SteelProcessed by Laser Additive Manufacturing

Marcos Vinícius Bento[1], Jurandir Marcos Sa de Souza[2], Juliane Ribeiro da Cruz[2], Alexsandro Rabelo[2], Henrique Rodrigues Oliveira[3]

[1]Instituto Senai de Inovação em Processamento a Laser (*L-PBF*) , [2]Instituto Senai de Inovação em Processamento a Laser, [3]Instituto Senai de Inovação em Processamento aLaser (*Manufatura Aditiva*)

e-mail: marcos.bento@sc.senai.br

Additive manufacturing (AM) processes are used for rapid prototyping and production of customized parts with complex geometries. Laser Powder Bed Fusion (L-PBF) provides superior finishing and geometric precision, while laser Directed Energy Deposition (L-DED) is capable of producing parts with large dimensions at a fast deposition rate. AISI 410 martensitic stainless steel has high mechanical strenght and corrosion resistance, making it ideal for applications ranging from cutlery to pump and valve parts. To improve the processability by AM, a low-carbon content variation of this alloy (410L) is preferable. In this study, the microstructure and mechanical properties of 410L samples produced by L-PBF and L-DED were evaluated in as-built and heat-treated conditions, and compared to those of a commercial 410 substrate. The results show that all AM samples had superior yield and ultimate tensile strengths due to the fast cooling rates, resulting in a refined microstructure compared to the commercial 410 material. However, the commercial alloy had the highest elongation, indicating superior impact energy absorption. While samples produced by AM had lower impact energy absorption in the as-built condition due to directional solidification and grain boundary segregation of brittle phases, heat treatment partially recrystallized and redistributed the phases, significantly improving the material''s toughness. Heat-treated L-PBF samples had the highest toughness values of up to 70 J (compared to 40 J for the substrate), while heat-treated L-DED samples had the highest yield and ultimate tensile strengths of 674 and 845 MPa, respectively (compared to 368 and 644 MPa for the substrate). The results indicate that additively manufactured samples havea competitive mechanical performance in comparison to commercial materials, contributingto a better understanding of the intricacies of the processing and metallurgy of this material.

Non-equilibrium solidification of the ferromagnetic Fe-Si6.5 alloy: microstructure and physical properties

Diogo de Campos Fernandes[1], Piter Gargarella[2], Vitor Eduardo Pinotti[2], Angelo F Andreoli[3]

[1]Univerdade Federal de São Carlos (*DEMa*) , [2]Univerdade Federal de São Carlos (*Department of Materials Engineering*) , [3]Univerdade Federal de São Carlos (*Engenharia de Materiais*)

e-mail: diogofernandes@estudante.ufscar.br

Fe-Si6.5 (%wt.) is a ferromagnetic alloy with attractive magnetic properties, such as near-zero magnetostriction, near-zero magnetocrystalline anisotropy, and high electrical resistivity. These properties, in combination with the low price, make the Fe-Si6.5 (%wt.) alloy an interesting option for energy storage and transmission. However, processing difficulties related to limitations of obtaining sheets with thicknesses of 0.1-0.3 mm, which is ideal to reduce eddy current losses, made unfeasible the application of the alloy on large scale. This limitation occurs by the brittle character of intermetallics B2 and D03 phases that are formed during cooling in quasi-thermodynamic equilibrium. Recently, the processing of Fe-Si6.5 (%wt.) by selective laser melting (SLM) has been proposed, in which extreme cooling rates are achieved. In this way, the investigation of non-equilibrium solidification is of great interest. Thus, the present study evaluated the effect of liquid undercooling on microstructural evolution, phase transformations, and how these characteristics influence the magnetic properties of Fe-Si6.5 (%wt.) alloy. The metastable solidification regime was achieved using electromagnetic levitation (EML) and glass fluxing techniques. The microstructure of the solidified samples was studied by microscopy techniques and X-ray diffraction, and the thermal behavior of the samples was evaluated. The effects of rapid solidification on the magnetic properties, namely the hysteresis loops, were investigated. In conclusion, this work aims to provide a fundamental understanding of the behavior of the Fe-Si6.5 (%wt.) ferromagnetic alloy when processed by non-equilibrium solidification methods.

Parametric modeling for Additive Manufacturing: software comparison and applications

Laureana Stelmastchuk Benassi Fontolan[1], Leonardo Mendes Ribeiro Machado[1], Marcelo Fernandes Oliveira[1], Pedro Yoshito Noritomi[1]

[1]Centro de Tecnologia da Informação Renato Archer (*LAprint*)

e-mail: laure.stelmastchuk@gmail.com

Parametric modeling enables fast creation of models by algorithm-driven digital model generation, the basis of generative design (GD). For prototyping it allows professionals to quickly adapt models to fit their purposes, thus accelerating product conceptualization and substantiation. Although Additive Manufacturing (AM) makes it possible for complex geometries to be fabricated, a fundamental part of AM in the GD context is obtaining the parametric digital 3D models. The aim of the present work is to generate parametric structures using different softwares available and compare the process and results. The Renato Archer Information Technology Center is a Brazilian research center located in Campinas, state of São Paulo, it supports academic and industrial research with AM techniques such as SLS, FFF, EBM, Polyjet, Binderjet and Waxjet through the 3D printing Open Lab (LAprint). A methodology for generating parametric models was developed for the free softwares Blender and OpenSCAD and it was compared to the process with another softwares available, such as Grasshopper, nTopology and Altair GD solutions. Blender visual programming Geometry Nodes is similar to Grasshopper, a graphical algorithm editor that can be integrated McNeel Rhinoceros. Blender also allows the user to automate tasks through python scripting and have the feature Vertex Groups to select portions of the model to be optimized similar to nTopology features. The parametric structure generation process comparisons between softwares presented in this study summarizes the possibilities in different softwares and brings a prominent free software option for GD in the AM context. An essential feature of the digital 3D model is to be promptly adjusted to satisfy the requirements of dynamic projects and applications, achieving these goals using low cost software solutions can greatly improve research and industry applications for AM.

Processability of AISI 410L Stainless Steel by Laser Powder Bed Fusion

Marcos Vinícius Bento[1], Dan Alexander Gallego[2], Victor Lira Chastinet[2], Henrique Rodrigues Oliveira[3]

[1]Instituto Senai de Inovação em Processamento a Laser (*L-PBF*) , [2]Instituto Senai de Inovação em Processamento a Laser, [3]Instituto Senai de Inovação em Processamento aLaser (*Manufatura Aditiva*)

e-mail: marcos.bento@sc.senai.br

Metal additive manufacturing (AM) has been increasingly used in various sectors of industry. Among the different metal AM technologies, Laser Powder Bed Fusion (L-PBF) stands out for its ability to fabricate complex geometries with high dimensional accuracy and good surface finish. 410 martensitic stainless steel is widely used in a range of applications, from cutlery to pump and valve parts, owing to its high strength and corrosion resistance. However, the material''s brittleness poses a challenge in the L-PBF process, anda low-carbon variant, 410L, is preferred to improve processability. In this work, the properties of the gas-atomized powder were analyzed, a design of experiment was performed to establish an optimized set of L-PBF processing parameters and tensile specimens were then produced to assess the mechanical properties of this alloy processed by L-PBF. The powder presented relatively spherical particles, with an average circularity of 0.679, low internal porosity, few satellite particles, the chemical composition was in accordance with the specification and the particle distribution was 27.8-56.6 μm (D10-D90).To obtain the set of processing parameters, a central composite experiment was used, varying power, scanning speed and hatching. The data from the experiment was fed into a mathematical regression and the resulting set of parameters produced a sample with relative density of 99.95%. The specimens manufactured with this set of parameters exhibited a tensile and yield strength of 681 MPa and 621 MPa, respectively, with an elongation of 13.65%. However, the as-built material was found to be brittle upon impact, with an average absorbed energy of 3.9 J, which is attributed to the microstructure with elongated grains and brittle phases segregated in the grain boundaries. However, a heat treatment route was capable of increasing the impact strength to values as high as 70 J, with a small reduction in the tensile strength, to 619 MPa.

Production of conductive filaments based on recycled PLA for the development of 3D-printed electrochemical sensors

e-mail: ckalinke@unicamp.br

Additive manufacturing (3D printing) is an interesting tool for the development of electrochemical devices by using polymeric filaments with low cost, low waste, versatility, reproducibility for large-scale production, and portability [1, 2]. In addition, the combination of waste recycling and additive manufacturing allows the application of the circular economy approach. Based on this, this work proposes the use of recycled plastic waste toobtain new 3D-printed electrochemical cells and sensors. For this, waste coffee pods composed of biopolymer polylactic acid (PLA) were processed and re-extruded to manufacture conducting and non-conducting filaments. The first one was obtained by mixing PLA pellets, plasticizers, and carbon-based materials (i.e., carbon black and carbonnanotubes). Electrochemical cells and conductive electrodes were 3D-printed in different shapes and sizes, in which the cell was able to be recycled three times without printing issues. The conductive filament presented flexible and printable characteristics. The sensorprinted by using the conductive filament had better results compared to a PLA and carbonblack commercial filament, exhibiting faster electron transfer and higher electrochemicalsurface area [3]. Furthermore, the proposed sensors showed better electrochemical performance for the sensing of caffeic acid in coffee and tea samples and biosensing of yellow fever virus cDNA in blood serum samples. Thus, the produced materials showed lowproduction cost, thermal stability, and high-quality printability. Finally, this work reports thesynergism between sustainability, additive manufacturing, and electrochemical detections,aiming to achieve the circular economy concept.

e-mail: a.rossi@ufabc.edu.br

Additive manufacturing supports advances in materials'' processing adaptability using a disruptive way to fabricate complex-shaped structures by adding material systematically. Given this, the Laser Powder Bed Fusion (LPBF) is a technology capable of producing near net shape components based on fusion bondings obtained from a laser-based fusion of metallic powder particles. Even with the evolution of technologies involved in the process, controlling some critical attributes of the material processed with LPBF, like residual stresses, remains a matter to deal with during process planning. Residual stresses are intrinsic to material processing, but their components'' magnitude and behavior - tensile or compression - depend on the manufacturing route and its conditions. Regarding LPBF, thermal stresses are commonly expected due to the technology operation source. Thus, it is important to consider this property for LPBF parts to avoid residual stresses undesirable to the component''s final application. This study characterized the surface residual stress of maraging steel, an alloy applied in structural and tooling industries, using the of X-ray diffraction (XRD) technique. Differences in surface residual stresses could be seen depending on the processing conditions, and the main mechanisms identified for the residual stress generation were discussed. Finally, the proposed analysis contributes to LPBF process planning.

Retained austenite decomposition pathways in additively manufactured H13 hot-work tool steel

Eduardo Bertoni da Fonseca[1], Julián David Escobar Atehortua[2], André Henrique Guimarães Gabriel[1], Giovani Gonçalves Ribamar[3], Torben Boll[4,5], Éder Sócrates Najar Lopes[1]

e-mail: eduardobfonseca@gmail.com

In laser beam powder bed fusion (PBF-LB) of AISI H13 tool steel, the as-built microstructure develops a microsegregated solidification structure of elongated cells, in which retained austenite (RA) decorates the cell walls and the interior contains martensite. The inhomogeneous distribution of alloying elements locally stabilizes RA and affects the phase transformations upon heat treatment. Synchrotron X-ray diffraction, scanning electron microscopy, and atom probe tomography were used to study the RA decomposition kinetics in the 550-650 °C range. The as-built condition contains circa 20-26 vol% of RA due to microsegregation of C, Cr, V, and Mo. During heat treatment, two microstructural pathways were observed. At low temperatures (T 650 °C), isothermal transformation of RA into ferriteand coarse carbides occurs within 600 s of the isothermal soaking. Martensite overtempering occurs, along with the dissolution of the solidification structure, promoting softening.

This work was supported by FAPESP, CNPq, and CAPES. This research used resources of the LNLS/CNPEM (XTMS beamline) and LNNano/CNPEM (SEM and TEM facilities). APT experiments were performed at the KNMF/KIT. Specimens were produced at Omnitek.

Self-disinfecting photopolymerizable nanocompositesfor 3D printing: allying antiviral properties

Tamires da Silva Lima[1], Karina Maria de Souza Silva[1], Ivani Malvestiti[1], Petrus Santa-Cruz[1]

[1]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*)

e-mail: tamires.lima@ufpe.br

Nanostructured materials and their mechanisms of antiviral activity present efficacy in coatings and surface treatments for an expressive group of viruses [1]. Nanocomposites with self-disinfecting properties act in an active-passive way for applications in materials whose objective is the inhibition of microorganism growth and viral inactivation [2,3]. Thiswork reports the development of a self-disinfecting material based on copper nanoparticles(CuNP), copper oxide (CuONP), and hybrid phase (CuNP + CuONP) incorporated in photopolymerizable resin. The production of these photopolymerizable nanocomposites for 3D printing with potential self-disinfecting properties for antiviral activity aims to inhibition of virus propagation. Allying bioinspiration, these materials allow the exploration of different hierarchical structures by 3D printing technology through active-passive mechanisms. Therefore, CuNP and CuONP were synthed by two methodologies (chemical reduction via L-ascorbic acid and mechanochemistry) and presented average s of 18.3 nm (CuNP) and 8.3 nm (CuONP). The photopolymerizable nanocomposites were characterized by UV-vis, FTIR, DRX, and SEM. Antiviral tests were performed in collaboration with FIOCRUZ-PE, initially with a model virus (Zika virus), in a NB-2 biosafety level environment, and later tests with SARS-CoV-2 will be performed. Preliminary results show that the nanocomposites produced have antiviral activity and were able to inactivate the model virus analyzed.

Smart additives based on nanoparticles of mixed oxides derived from LDH in the crystallization of phases formed during cement hydration

Adriana Araújo Almeida[1], Rodrigo Morais Menezes Dos Santos[1], Caio Carvalho dos Santos[1], Valérie Briois[2], Sandra Helena Pulcinelli[1], Celso Valentim Santilli[1]

[1]Universidade Estadual Paulista / Instituto de Química, [2]Synchrotron Soleil

e-mail: adriana.a.almeida@unesp.br

Synthetic clays known as lamellar double hydroxides (LDH) are a class of multifunctional materials that, when added to cement, can contribute to the formation of the microstructure of hydrated cement. The thermal decomposition of LDH (400 500 °C) leads to the formationof nanocrystalline mixed oxides (MO), which can regenerate the lamellar structure in contact with water and anionic solutions, through the memory effect. The regeneration of the LDH lamellar structure directly influences the rheological behavior of the cement paste after the addition of MO particles, with the acceleration of paste consolidation in the first hours, indicating the potential application of these materials for 3D printing. Investigations using the time-resolved X-ray absorption spectroscopy demonstrated that the recovery of the ZnGa-HDL nanostructure was driven by a mechanism of nucleation and aggregativegrowth. In simulated concrete pore solution (pH 14) the formation of the LDH phase wasverified. Reconciling the memory effect and surface area (37 m2g□1), MO particles can actas nucleation points, contributing to the strengthening of the hydrated cement microstructure. For this, the formation of the hydration phases was monitored by X-ray diffraction for the cement paste containing ZnGa-LDH and the respective MO during 4 h andthe results demonstrated the acceleration of the hydration process, evidenced by the increase in the formation of the ettringite (AFt), especially for samples containing MO, indicating that regeneration of the LDH structure favors the kinetics for obtaining AFt. These results are interesting, since the AFt, formed in the first hours, is converted over timeinto hydrated calcium monosulfoaluminate (AFm), which has a layered structure similar tothat observed in hydrotalcite-type compounds. This makes it possible to correlate the effectof MO addition particles in the hydration phases with the structural changes of the cement.

The role of rheology in the development of bioinks for3D bioprinting

Paula Cristina Gomes Fernandes[1], Viviane Fajardo Filgueiras[1,2], João Henrique Lopes[1]

[1]Instituto Tecnológico de Aeronáutica (*Departamento de química*) , [2]Universidade Federal deSão Paulo

e-mail: paulacgfernandes7@gmail.com

The development of bioinks for 3D bioprinting relies heavily on rheology, which involves the study of flow and deformation of matter. Bioinks, specialized materials that act as ink in 3D printers, are used to precisely position living cells in complex patterns and shapes to create functional tissues and organs. To ensure successful 3D bioprinting, the rheological properties of bioinks must be carefully optimized. This involves ensuring that the ink flows smoothly through the printer nozzle [1], remains stable after deposition, and has mechanical properties that are compatible with the surrounding tissue environment [2]. Here, we evaluated the rheological properties, such as viscosity, storage modulus G’ and loss modulus G’’ of alginate-derived bioinks with different degrees of bioinorganic ion-mediated crosslinking, which are crucial for successful printing. By assessing the bioink over a wide range of process parameters, including temperature, pressure, feed rate, and nozzle geometry, we were able to determine its printing behavior. Our findings revealed that the network strength, shear-thinning, yield point, and thixotropy are key factors that govern bioprintability. Our research provides a comprehensive approach to bioink development anda highly reproducible and well-characterized procedure for printing with the newly developed hydrogel. Additionally, our work provides detailed insights into the relationship between printing parameters, rheological parameters, and short-term cultivation stability.

The Thermo-Calc Additive Manufacturing Module: An integrated Calphad-based FEM tool

Alisson Kwiatkowski da Silva[1], Andreas Markström[1], Amer Malik[1], Quang Minh Do[1], Johan Jeppsson[1]

[1]Thermo-Calc Software AB

e-mail: alisson@thermocalc.com

Today's state-of-the-art Finite Element (FEM) tools tend to use relatively simplified materials descriptions using handbook values that might have little dependence on chemistry or even temperature. Thermo-Calc has spent the last few years developing new models to predict thermophysical material properties to incorporate with CALPHAD-based materials descriptions. This is currently used to extract CALPHAD-based materials data for use in dedicated FEM codes and is now laying the foundation for our development of a completely integrated tool to simulate Additive Manufacturing (AM) processes. The AM Calculator is released in Thermo-Calc version 2023b, and it gives a unique possibility to address the problem of solidification during AM, where we obtain a unified treatment of both process parameters and chemistry-dependent thermophysical properties when solving the multi-physics problem of a moving heat source that melts and solidifies metal powder. The updated Scheil calculator allows for pre-generating a solidification profile, now also including evaporation properties, that can be saved into your own materials library, or used directly as input to the AM Calculator. Examples of the AM module applied to different material classes are shown.

3D-printed covalent immobilization-based carbon black immunosensors for portable electrochemical detection of SARS-CoV-2 spike S1 protein

e-mail: wilsonfernandes@estudante.ufscar.br

3D printing technology has gained ground due to its wide range of applicability [1]. Recently, 3D printing has played a significant role in the fight against the global pandemic event COVID-19 through decentralized and on-demand manufacturing of different personal protective equipment and medical devices, such as masks, valves, and swabs [2]. However, 3D printing technology is still considered recent and with great potential to be explored for the most diverse purposes, including the manufacturing of analytical devices [3]. The development of new conductive filaments contributes significantly to the production of improved electrochemical devices. In this sense, the fabrication of 3D-printed devices for the development of electrochemical (bio)sensors has become an almost unexplored field of great interest. Therefore, this work has presented the production of a new 3D-printed electrochemical immunosensor, based on the covalent immobilization of antibodies on electrodes obtained from lab-made conductive filaments, composed of carbon black and polylactic acid, for the detection of the spike S1 protein of the SARS-CoV-2 virus. It was possible to create an immunosensor without the use of metallic particles since the surface of the additively built sensor had readily available carboxylic groups. Under the optimized parameters, the immunosensor presented a linear range of 0.01 to 4.5 nmol L^{-1}, and a detection limit of 2.7 pmol $L^{-1}$for spike S1 protein. Therefore, a highly viable option to be used as a point-of-care device, the 3D-printed immunosensor was entirely developed for in loco application and all findings were obtained from portable equipment.

To overcome the environmental concerns related to climatic changes and limit the atmospheric concentration of carbon dioxide (CO_2), improved gas-separation processes such as pressure-swing-adsorption (PSA) through the use of adsorbents for CO_2removal and H_2-purification are of great interest. In this research, sugarcane-bagasse ash (SBA), an agroindustrial by-product, was used to manufacture a sustainable adsorbent from biomass-activate-carbon/zeolite porous composites using 3D-printing techniques. This alternative type of adsorbent was prepared by incorporating from 1.0 to 10.0 wt % of SBA-activated carbon into the SBA-zeolite-porous monoliths, followed by hydrothermal treatment in order to improve the specific surface area and micro-meso porosity characteristic, as well as improve CO_2affinity. In addition, SBA-derived zeolite-porous monoliths were 3D-printed with designed configuration to be used as standard-adsorbent for comparison. Optimized SBA-activate-carbon/zeolite-inks containing different additives (2.5-10.0 wt.%) of halloysite clay (HCT), as plasticizer, (1.0-4.5 wt.%) of methylcellulose (MC), as thickener and (1.0-5.0 wt.%) of poly(ethylene glycol) (PEG), as lubricant, respectively, were prepared. The three-dimensional monoliths were freeze-dried at (-100 to -15°C) for 1 h and dried for 24h at ambient conditions. Afterward, samples were fired at 650 °C for 1 h at a heating rate of 10 °C/min. Fired monoliths were transferred to a Teflon capsule containing an alkaline solution (2.5 wt.% of $Al(OH)3$ and NaOH 3M) and surfactants species (sodium dodecylbenzenesulfonate) in order to driven 13X-zeolite structure, and then, deposited into stainless-steel autoclave at 105°C ± 5°C (for 72-160 h) to provide the precipitation of zeolite crystals in situ. The specific surface area ~564 $m^2g^{-1}$was determined by Brunner- Emmet-Teller analysis (BET). Preliminary results indicate the viability of these SBA- composites as CO_2capture and H_2-purification.

3D printing of hydrogels for treatment of cutaneous leishmaniasis

Eronildo Alves Pinto Junior[1], Letícia Bazílio Rosa[2], Marcos Akira dÁvila[1], Danilo Ciccone Miguel[2], Aline Mara dos Santos[3]

[1]Universidade Estadual de Campinas (*Materials and Manufacturing Processes*) , [2]Universidade Estadual de Campinas (*Parasitology*) , [3]Universidade Estadual de Campinas (*Structural and Functional Biology*)

e-mail: eronildo.ufes@hotmail.com

Leishmaniasis is a tropical disease caused by the parasite Leishmania and transmitted through sandfly bites. The current treatment options are limited due to the high toxicity of most drugs. However, 3D printing (3DP) technology has emerged as a promising approach for treating leishmaniasis. Tea tree oil (TTO), derived from the *Melaleuca alternifolia* plant used for its medicinal properties, has antimicrobial properties against various bacteria, viruses, fungi and parasites [1]. The purpose of this work was, from 3DP, to produce nanocomposite hydrogel *scaffolds* composed of alginate, cellulose nanocrystals, and collagen with incorporated TTO for the treatment of cutaneous leishmaniasis. To our knowledge, the use of 3DP to obtain a hydrogel construct for treating cutaneous leishmaniasis has yet to be reported in the literature. In vitro studies were carried out to investigate the activity of TTO dissolved in culture medium after 24 hours of incubation. Half maximum effective concentration (EC50) was obtained with 0.08% TTO against L. amazonensis and L. braziliensis promastigotes. Against RAW 264.7 macrophages, half maximal cytotoxic concentration (CC50) was 0.14%, indicating approximately 2-fold greater selectivity against the parasite. In the evaluation of the impregnated scafolds, a dose-dependent response was observed with the inhibition of 90%, 85% and 70% of L. amazonensis promastigotes after 24h of incubation with scafolds impregnated with 10%, 5% and 2.5%, respectively, of TTO. Tea tree oil has shown good leishmanicidal activity and is a promising treatment against cutaneous leishmaniasis.

Additive manufacturing of layered Fe-Si composites for soft magnetic applications: A critical review

Angelo F Andreoli[1], Vitor Eduardo Pinotti[1], Piter Gargarella[1]

[1]Univerdade Federal de São Carlos (*Materials Engineering*)

e-mail: angelo.andreoli@ufscar.br

Better-performing electrical machines rely on the development of soft magnetic materials with fewer losses owing to hysteresis and eddy currents. Electric steels (Fe-Si) have long been used in electrical machine cores as a ferromagnetic material. Despite their inexpensive cost, Fe-Si steels with Si concentrations up to 3.2% by weight have low electrical resistivity, resulting in high eddy current losses. As the Si concentration increases, the electrical resistivity increases, and the magnetic properties are improved, namely near-zero magnetostriction, and near-zero magnetocrystalline anisotropy at 6.5 Si wt. %. However, the material becomes brittle, making the production process more complicated. To boost eddy current resistance, the core is made of thin sheets of Fe-Si steel with an insulating layer between each consecutive lamination. This geometric arrangement can be replicated by the laser powder bed fusion processing, which produces nearly completely dense metallic components layer by layer straight from computer-aided design data. This contribution critically analyzes the state-of-the-art progress concerning the fabrication of layered Fe-Si composites by additive manufacturing for soft magnetic applications. Some key topics requiring attention for further development will be highlighted and discussed.

Acknowledgments: Angelo Fernandes Andreoli - FAPESP 2021/12056-7; Vitor Eduardo Pinotti - FAPESP 2022/05528-2; Piter Gargarella - FAPESP 2021/12056-7, 2022/05528-2.

Additive manufacturing of TPU/HNT nanocomposites: Influence of rheological behavior on printing quality

Maria Clara Garcia Pazini[1], Juliano Marini[1]

[1]Univerdade Federal de São Carlos (*DEMa*)

e-mail: mariaclarag.pazini@gmail.com

Thermoplastic polyurethanes, TPUs, are polymeric materials with elastomeric properties and processability like that of thermoplastics, being a material of choice for various biomedical applications due to their flexibility, biocompatibility, biostability and electrical insulation [1]. The use of halloysite nanotubes (HNT) as reinforcing filler in TPU nanocomposites has been studied since this nanoparticle has high aspect ratio, good mechanical properties, biocompatibility, and hollow tubular structure [2]. Additive manufacturing (AM) can be used for forming biomedical devices and, therefore, the production of 3D printed devices based on TPU/HNT presents great potential. In this work, filaments of TPU and TPU/HNT (95/5 and 90/10 w/w) were obtained by twin-screw extrusion. The influence of HNT on the thermal (DSC and TGA) and rheological behavior was measured. The filaments were molded in type IV (ASTM D638) tensile specimens by AM using a Fused Filament Fabrication (FFF) printer and the printing quality (visual inspection and dimensional stability) was correlated to the rheological properties. The presence and content of HNT did not significantly influence the thermal behavior of the TPU; however, the rheological behavior was greatly affected, since the higher the HNT content, the greater the G'' and G” at low oscillation frequencies, in addition to a significant increase in pseudoplasticity in the nanocomposites, indicating a lower viscosity and elasticity at high strain rates, typical of the 3D printing process. Despite the reduction in the printing quality of the nanocomposites when compared to TPU, a good dimensional accuracy between the printing pattern and the printed specimens was obtained.

Analysis of characteristics and application potential of paving bricks

RODRIGO DOS SANTOS GALVÃO DE ARAUJO[1], JOSÉ MILTON ELIAS DE MATOS[1]

[1]Universidade Federal do Piauí

e-mail: engrodrigogalvao@gmail.com

In antiquity, agropastoral activities were carried out by animals and the lack of quality of transport routes made people look for ways to improve. The first reports of the use of ceramics as road coverings date back to 5000 BC. In Brazil, the first reports of the use of paving with the use of ceramic material date back to 1940, in Acre; due to the lack of raw material, such as stones, and the abundance of clay, the use of this type of pavement has become quite viable. The paving brick, also known as adoquim , is a product based on clayey mass and non-plastic materials. Depending on its production process and raw materials used, the paving brick is capable of withstanding different types of traffic, ranging from pedestrian sidewalks to roads of varying use. The research aims to evaluate, through a bibliographic review, the characteristics and the application potential of paving bricks. As a result, it is possible to see that the product has some advantages such as durability; have different surface designs or configurations; it has a fast operating time; good physical properties, as they are resistant to fuels, greases, oils and lubricants; good mechanical properties, such as high compressive strength, resistance to combined bending-traction efforts, hardness, abrasion resistance and slip resistance; low cost of maintenance and conservation [1]. With the research, it is possible to conclude that adoquim is an innovative product, still not widespread in Brazil. Because of this, the country does not have legislation or norms to standardize and guarantee their technological quality. However, countries like Spain, Colombia and the United States already have regular application of the material, framed in local norms.

Assessing the buildability of cementitious matriceswith chemical admixtures designed for 3D printing

Jairon Gomes da Silveira[1], Kevin de Moura Cerqueira[1], Ruan Carlos de Araújo Moura[1], José Renato de Castro Pessôa[2], Marcelo Tramontin Souza[1]

[1]Universidade Estadual de Santa Cruz (*DEC*) , [2]Universidade Estadual de Santa Cruz (*Materiais*)

e-mail: jgsilveira.egc@uesc.br

The principle of 3D printing involves the layer-by-layer construction of structures from a digital model. To determine the feasibility of using cement mixtures for 3D printing by robocasting, rheological properties in the fresh state and mechanical strength in the hardened state are crucial influencing factors [1,2]. This study presents a roadmap for evaluating the buildability of cement mixtures. Various tests were conducted on cement pastes with different water/cement ratios (ranging from 0.26 to 0.36) and chemical admixtures, including a superplasticizer (at 0.25 wt.% and 0.5 wt.%) and a setting accelerator (at 1 wt.%, 1.5 wt.%, and 2 wt.%). The tests involved overlapping molded filaments to analyze load-bearing capacity and filament deformation at different time intervals (5, 10, 15, and 20 min). The buildability was considered adequate for mixtures capable of supporting 12 layers and with a thickness variation of less than 10%. Additionally, a slump flow test was conducted to correlate with the buildability. The results revealed that mixtures without additives with water/cement (w/c) ratios ranging from 0.26 to 0.32 were buildable for time gaps of 10 min or longer. For w/c of 0.34, the buildability is achieved with time gaps of 15 min or longer. Smaller ratios were difficult to mix and larger ratios provided minimal load-bearing capacity. The chemical admixtures proved beneficial in reducing time gaps and filament deformation, especially for 1.5 wt.% or more of setting accelerator and up to 0.25% of superplasticizer. Results from the slump flow test indicated that samples with a spreading diameter below 180 mm exhibited acceptable buildability.

e-mail: kksousa12@gmail.com

Natural materials have been studied as the best alternative for application as biomaterials due to their characteristics such as: biocompatibility, biodegradation and low cost [1]. Recently, natural materials extracted from marine sponges such biosilica (BS) and spongin (SPG) have shown positive results in tissue regeneration [2]. Moreover, 3D printing have been showing great effectiveness in producing scaffolds with natural materials [3]. So, the aim of the present study was to evaluate and compare the physicochemical and morphological characteristics of 3D printed scaffolds of BS and BS/SPG. The marine sponges Dragmacidon reticulatum and Aplysina fulva were used to BS and SPG extraction, respectively. For the manufacture of scaffolds, the Octopus™ - 3DBS bioprinter was used. The physicochemical and morphological characteristics were analyzed by FTIR, evaluation of mass loss and porosity, pH measurement and scanning electron microscopy. In the FTIR, BS peaks were similar with silica materials and SPG peaks demonstrated similarity with collagen peaks. The porosity of the scaffolds was between 44% and 90%. The mass loss rate of the BS scaffolds was between 6% and 60% while in BS/SPG scaffolds it was between 6% and 66%. In the pH measurement, the BS scaffolds maintained their pH between 5.64 and 7.18 while the BS/SPG scaffolds maintained between 5.81 and 6.10. SEM demonstrated that the BS spicules are very evident and the SPG fibers mix with them. With these results it is possible to conclude that BS and BS/SPG scaffolds have characteristics that facilitate the construction of porous scaffolds with controlled degradation. Moreover, they also maintain a pH favorable to cell growth.

Cationic etherification modification of cassava starch: biocidal and physicochemical properties

Guilherme Ribeiro Carvalho[1], Amanda Miki Kudaka[2], Rafael Affonso Netto[2], Liliane Maria Ferrareso Lona[2]

[1]University of Campinas (*Department of Bioprocesses and Materials Engineering, School of Chemical Engineering*) , [2]Universidade Estadual de Campinas (*Faculdade de Engenharia Química*)

e-mail: gr.carvalho@yahoo.com.br

Starch is the most abundant biopolymer in the world after cellulose, found in roots, cereals, legumes, tubers, fruits, and seeds. The main commercial sources of starch are potatoes, corn, wheat, rice, and cassava. Cassava starch is considered a biopolymer with high potential for applications in various industrial sectors. It is present in the composition of several industrial products, but stands out in the paper and cardboard, personal hygiene, pharmaceutical, chemical and textile industries, and in the production of plastic packaging [1].

In view of the wide industrial application of cassava starch, the number of researches is increasing with the aim of providing new physicochemical characteristics to this biopolymer [2]. In this context, the cationization of cassava starch by quaternary ammonium salts, through the chemical reaction of quaternization, is shown to be an interesting and promising alternative, with the aim of conferring mainly biocidal properties to the starch.

In this study, cationic starch was prepared by etherification reaction of glycidyl-trimethylammonium chloride (GTMAC) and cassava starch. The synthed cationic cassava starch showed efficacy against SARS-CoV-2 virus and satisfactory inhibitory activity against Escherichia coli and Staphylococcus aureus bacteria, making it a new material with potential application in several biotechnological areas. The physicochemical characterization of cationic cassava starch was carried out by elemental analysis (C,H,N), Fourier-transform infrared spectroscopy (FT-IR), thermogravimetric analysis (TGA), and nuclear magnetic resonance (C13 NMR).

Metalúrgica e de Materiais, Escola Politécnica da Universidade de São Paulo*), [2]Fundação Universidade Federal da Grande Dourados (*Faculdade de Ciências Exatas e Tecnologia*), [3]Universidade de São Paulo (*Escola Politécnica - Engenharia Metalurgica*), [4]Universidade de São Paulo, [5]Universidade de São Paulo (*Departamento de engenharia metalúrgica e de materiais*), [6]Escola Politécnica de Universidade de São Paulo (*Departamento de engenharia metalúrgica e de materiais*)

e-mail: coelho.rezende@gmail.com

In this work the corrosion resistance of as-produced 17-4 PH stainless steel samples fabricated by additive manufacturing (AM) using Laser Power Bed Fusion (PBF) and Laser Directed Energy Deposition (DED) technologies were compared. In these two AM techniques pieces are produced layer-by-layer; however, whilst in PBF a high-energy laser beam scans areas previously covered by the powder producing the net-shaped pieces, in DED the laser beam is focused on a specific area, and the powder is simultaneously injected through a nozzle, resulting in different thermal history and microstructural patterns. The two producing technologies also differ by their cooling rates and geometric tolerances [1]. For the electrochemical measurements, a 3-electrode cell was used, with the samples (working electrode), the SCE (reference electrode) and a platinum spiral (auxiliary electrode) in NaCl 5% (m/m). In the experimental procedure, monitoring of the OCP was performed, consecutively, during 12h, and EIS measurements were acquired after each period (12 h and 24 h of immersion). The OCP values at 12h and 24h were: EOCP(PBF)= -0.11 /-0.07 V and EOCP(DED)= -0.13 / -0.11V, respectively. Electrical equivalent circuit fitting of the EIS diagrams did not show relevant variation between the samples. Nevertheless, potentiodynamic polarization curves after 25h showed Epit +0.41 V and +0.24V to PBF and DED, respectively, indicating a higher resistance to pitting on PBF sample. Microstructural analyzes carried out before and after the electrochemical tests showed different pitting mechanisms that are correlated with thermal stress and cooling patterns during samples' production. In PBF processed samples, pits nucleate in the centerof the cell-like grain typical of this AM technology. On the other hand, those processed byDED present pits starting along the melt tracks.

Concrete blocks subjected to ballistic impact testing: Reinforcement performance and identification of local and global damages Wesley Machareth Lisboa1,2, Diego Pinheiro Sodré1,2, Fernanda Gomes Pixioline1,2, Joaquim Teixeira de Assis1,2, Joel Sanchez1,2 1Universidade do Estado do Rio de Janeiro, 2Instituto Politécnico de Engenharia e-mail: wesley.m@pm.rj.gov.br, diego.p@pm.rj.gov.br, fernanda.g@pm.rj.gov.br, Joaquim.iprj@gmail.com, jsdominguez@iprj.uerj.br Statistics published by Public Security Agencies justify the increasing demand for construction methods that enhance the sense of security [1], marking recent years with a significant growth in investments in protection systems. Concrete, in turn, proves to be an important tool for developing products with this purpose and shows promising results when subjected to ballistic impact. This study presents the performance of concrete samples, with and without internal reinforcement, with an average compressive strength of 40 MPa, subjected to ballistic impact caused by projectiles of caliber 0.40", 5.56 mm, and 7.62 mm. For the experiment, three concrete samples were produced, one with internal reinforcement of aramid fiber, another with internal reinforcement of 1020 steel, and another without internal reinforcement. All samples received the Sika® Concrete Forte plasticizer as an additive. The specimens were producedand classified according to adaptations of ABNT/NBR 15000:2020 and ABNT/NBR 5983:2015 standards. The samples were subjected to impacts fired at a distance of fifteenmeters. As the tests were carried out, the occurrence of local damages, such as the formation of craters and tunnels, and global damages, such as crack propagation and material detachment on the impact faces of the samples, were verified [2]. Fragmentation on the opposite face of the impact was also observed in one of the samples. These resultsdemonstrate that concrete, even without reinforcement, exhibits good re

DEFINITION OF PROCESS PARAMETERS BY DIRECT ENERGY DEPOSITION (DED) FOR AISI 431L STAINLESS STEEL GAS TURBINE BLADES

Caroline Cristine de Andrade Ferreira[1,2], Johan Sebastían Grass Nuñez[3], Rafael Humberto Mota de Siqueira[2], Evandro Guilherme de Souza Zanni[1,2], Rafael Dei Tós Barreto[1], Daolun Chen[4], Milton Sergio Fernandes de Lima[2]

e-mail: carolinecaferreira@gmail.com

The objective of this study was to define a process map for the growth of gas turbine blades using direct energy deposition. For additive manufacturing, AISI 431 L stainless steel powder was used, and the blades were grown on an AISI 304 L steel substrate. In gas turbines, the blades are composed of alloys resistant to high temperatures and are considered to have the highest specific cost [1]. The blades are subjected to a corrosive environment, at high rotation and high temperatures [2]. DED depositions were carried out using BeAM modulo 250, equipped with linear motors on five axes. The process control was carried out using Siemens 840D equipment, while the laser source was a Yb:glass, with 1kW of power, from IPG Photonics. The powder sprinkler system (head) and powder distributor belong to BeAM. Thirty-six parameters were reproduced with only one bead, and the process variables were scanning speed from 1800 mm/min to 2200 mm/min, power from 300w to 550w, and powder mass flow from 4,7g/min and 8,42g/min. After performing the thirty-six parameters, the six best parameters were chosen to be reproduced, considering the best adhesion between bead and the substrate, a more homogeneous bead, and one that promotes complete fusion of the bead. Through parameterization, it was possible to grow the blade by LP-DED, without limiting the number of layers. From the preliminary analyses, the parameters used to produce Six different supersonic airfoils were: 2000 mm/min speed, 450 W powerand 8.42 g/min powder mass flow. The choice of these parameters is due to the volumetric defects and hot cracks between the layers.

e-mail: suzannypaiva@hotmail.com

Produced water (PW) in oil production operations contains both dispersed and emulsified oil. The Total Oil and Grease (TOG) in water is a parameter controlled daily for disposal or reinjection, and have limits stipulated by environmental agencies. The reference method accept by IBAMA is made through the partition-gravimetric, which is very susceptible to quantitative errors and not practical. To control the quality of PW on oil platforms, different benchtop analysers are used for TOG measurements. Studies related to new technologies concerning fluid monitoring are important to industry and acoustic techniques can be likely succeed for this purpose. The aim of this work was to develop model dispersed systems, simulating PW, with known and controlled physical-chemical properties, in order to facilitate the development of an assertive methodology based on acoustic properties to estimate TOG values. Concentrated emulsions of oil (hexadecane) in water (O/W) were prepared in varying proportions of O and W with a mixture of non-ionic surfactants. From there, dispersed systems with low oil content (oil range from 5 to 1,000ppm) were obtained. All systems were characterized in terms of visual stability, viscosity and distribution and size of the drops as a function of time. The correlation between acoustic properties and TOG is made through transducers coupled to an apparatus built by 3D printing. The results showed assertiveness in the proposed method and in the choice of constituents for the stable and reproducible dispersed system preparation. e-mail: ramos_rr@ime.eb.br

H13 tool steel is used to produce dies and molds due to properties as wear resistance and toughness, stable under high temperature [1, 2]. Traditionally, they are produced through several machining steps, followed by heat treatments to control microstructure and achieve desired properties [1]. Direct Energy Deposition (DED) additive manufacturing (AM) is gaining considerable attention in tooling fabrication due to its capability to produce customized geometries, complex cooling systems and functionally graded microstructures [1, 2]. DED process parameters are critical to the final properties [1]. Therefore, the purpose of this study was to evaluate the number of layers influence in depth penetration and geometrical dilution with fixed energy density, through cross-section observation, using optical and scanning electron microscopy, and microhardness analysis. The present work used H13 steel powder, water atomized in a Brazilian company, deposited through DED/AM over a microalloyed hot rolled steel sheet, generating a stack of layers, whose overlap involved an in-layer post heating [2], remelting part of the upper tracks and heat treating the bottom ones [1]. This resulted in columnar grains morphology close to substrate due to epitaxial growth, and reduced columnar grains length with changed microhardness values in re-heated areas at layers intersections, as expected [2]. Finally, despite some observed voids, it is concluded that the deposition was adequate for DED process first stage anchoring the H13 steel deposit in the substrate as function of the suitable geometrical and chemical dilution depth at first layer-substrate interface [3].

Recent advancements in additive manufacturing allowed the development of titanium parts with promising mechanical properties and complex geometries. The process also allows for controlled material distribution, which can be utilized to produce composite materials with distinct characteristics, resulting in a product with superior properties. This study investigates the reinforcement effect of adding intercalated layers of varying thicknesses (150 µm, 300 µm, and 450 µm) of Ti-6Al-4V alloy to a CP Ti matrix with a fixed thickness of300 µm. The samples were produced by the laser powder bed fusion (L-PBF) technique using a Yb:YAG laser with a power of 209 W, combined with a scanning speed of 700 mm/s. The microstructural analysis of the composites was performed through optical microscopy, scanning electron microscopy, and energy dispersive spectroscopy. The mechanical properties were evaluated by Vickers microhardness and compression tests. The high cooling rates lead to α' phase provoked by a martensitic transformation of the β phase. CP Ti layers have a Vickers hardness of approximately 255 HV, while the average Vickers hardness of the Ti-6Al-4V layers was found to be 350 HV. Compression tests showed a yield strength of about 1000 MPa, allied to a strain of about 45%. The results suggested the possibility of multi-material processing, tailoring the properties of the products according to the layer thickness.

Recently, the manufacturing of Ti alloys has seen significant evolution, thanks to the evolutions in additive manufacturing (AM) technology. This approach now allows for the creation of a vast array of products with intricate shapes and compositions, by applying a layer-by-layer deposition method. One of the most efficient AM techniques is laser powder bed fusion (L-PBF). It selectively melts metallic powder with a laser beam source. In general, the feedstock processed by L-PBF corresponds to pre-alloyed powders. If different powders with different mechanical behaviors are mixed and used as feedstock, a hybrid microstructure can be achieved [1]. The mixed powders can produce unique microstructure features, such as the formation of micro-regions rich in a particular component within a distinct matrix. In this work, a mixture of two different powders, corresponding to the ductile Ti-42Nb (wt%) alloy and the high mechanical strength Ti-5553 alloy, was utilized as feedstock. They were mixed in an eccentric rotary mixer. The samples were printed on an OmniSint-160 machine equipped with Yb:YAG fiber laser. The obtained samples were heat treated to produce regions with different mechanical features and characterized using scanning electron microscopy, X-ray diffraction, differential scanning calorimetry and nanoindentation tests. The results obtained suggested the formation of compositional microregions in the printed material, which led to heterogenous mechanical behavior after the aging heat treatment.

Enzymatic oxidation of lignosulfonates for aldehyde-free adhesive formulation

Uirajá Cayowa Magalhães Ruschoni[1], André Ferraz[2]

[1]Escola de Engenharia de Lorena - Universidade de São Paulo (*Departamento de Biotecnologia Industrial*) , [2]Escola de Engenharia de Lorena - EEL/USP (*Departamento de Biotecnologia Industrial*)

e-mail: ucmruschoni@usp.br

New products obtained from biomass biorefining can become an economically viable and environmentally sustainable reality. Product diversification in the biorefinery portfolio, including lignosulfonates and oligosaccharides, besides glucose and xylose can contribute to the techno-economic viability of biorefineries. As lignosulfonates are phenolic compounds, enzymatic oxidation can increase their molecular mass adding value to the final products. The present study aimed to evaluate the laccase-initiated oxidation of lignosulfonates from different plant materials (conifers and grasses), allowing application as an aldehyde-free adherent matrix for wood fibers. Enzymatic oxidation systems of lignosulfonates, both from conifers and sugar cane, using Trametes versicolor laccase demonstrated an increase in the molar mass of the treated lignosulfonates. For conifers, the molar mass increased from 1.9 kDa to 5.4 kDa, while the oxidation of sugar cane lignosulfonate increased from 1.1 kDa to two majors products with increased molar masses of 22.2 kDa and 2.8 kDa. This reaction system has been explored in fibers adhesion studies. Enzymatic oxidation of eucalyptus fibers promoted adhesion via oxidative crosslink of lignin residues. Unexpectedly, the presence of lignosulfonates, both from conifer and sugarcane bagasse, reduced the adhesion effect, most likely due to the solubility of the enzyme and the lignosulfonate having driven the radical coupling reactions in the aqueous medium and not on the fiber surfaces. This fact is evident when observing a profile of molar mass increase of the lignosulfonate collected in the washing water of the adhered fiber, being 3.2-fold for conifer lignosulfonate and 2.5-fold and 14.3-fold for sugarcane lignosulfonate. This adversity is being overcome by studying reaction systems with low moisture content forcing polymerization reactions to occur at the fiber surfaces.

Evaluation of the influence of different molecular weight polydimethylsiloxanes on the aggregation ofasphaltenes by atomic force microscopy

Mariana Teixeira Mendes[1], Rafael Farias Perez[2], Claudia E Mansur[3], Osvaldo Karnitz Júnior[4]

[1]Universidade Federal do Rio de Janeiro (*COPPE*) , [2]Universidade Federal do Rio de Janeiro (*IMA*) , [3]Universidade Federal do Rio de Janeiro, [4]CENPES/Petrobras

e-mail: mariana.mendes@coppe.ufrj.br

During oil production, undesirable foam formation occurs, which is stabilized by surfactants naturally present in oil, called asphaltenes. Currently, to remedy the problem of foam, polydimethylsiloxanes (PDMS) are used [1]. Therefore, the present work aims to evaluate the performance of PDMS of different molar masses in the formation of asphaltenes agglomerates using atomic force microscopy (AFM). As a result of the AFM images, it was possible to observe that PDMS interferes in the packing of asphaltenes, showing that the efficiency of these PDMS as defoamers is directly linked to the action of these products in the agglomeration of asphaltenes at the oil/air interface.

e-mail: bruno.fertig@posgrad.ufsc.br

Additive manufacturing (AM) of composite magnets using Laser Powder Bed Fusion (L-PBF) has shown great potential for achieving complex geometries and custom designs with high precision [1]. However, the porosity and magnetic properties of the final magnets are highly dependent on the processing parameters and feedstock characteristics [2, 3]. In this study, we explored the replacement of the polymeric matrix of the composite matrix with a metallic binder to improve density and magnetic properties. The feedstock, comprising Nd-Fe-B powder and polyamide-12 powder, was laser processed into low-density bonded magnets, which were then subjected to a sintering heat treatment. A systematic study was carried out to evaluate the change in magnetic properties of composite Nd-Fe-B magnets obtained using L-PBF. It was observed that the use of a rare-earth-based alloy metallic binder and the subsequent sintering heat treatment substantially increased the coercivity values from around 50 kA/m to more than 500 kA/m. This was due to the microstructural interactions between the infiltrated metallic phase and the ferromagnetic particles, altering the coercivity-induced mechanisms. This study sheds light on how microstructural changes introduced after the L-PBF process can improve magnetic properties, opening up new avenues for the design and development of high-performance magnetic materials for additive manufacturing.

e-mail: robertahmendonca@ufrrj.br

The destruction of bone microarchitecture characterizes osteoporosis, loss of mass, decreased bone strength, and increased risk of fractures. Bisphosphonates, for example, sodium alendronate (ALD), are usually applied to treat osteoporosis [1]. ALD presents some collateral effects in oral and intravenous administration. Among them, it is possible mention: irritation of the esophagus, fevers, ocular inflammation, and mandibular osteonecrosis. Polymeric materials play an essential role in biomaterial production for bone tissue regeneration. Thus, combining the appropriate polymer with drugs is critical to producing a suitable drug delivery system. Polycaprolactone (PCL), a biocompatible polymer, has been used in additive manufacturing techniques [1]. Chitosan (Chi) is a polysaccharide widely studied for drug delivery applications. In this work the hot melting extrusion (HME) technique was applied to produce PCL/Chi/ALD filaments. This filament was analyzed by scanning electron microscopy (SEM) and Fourier infrared spectroscopy (FTIR). SEM images characteristics of all materials present in the samples. FTIR analysis shows bands related to PCL, Chi, and ALD, showing that the material's chemical properties were unaffected and no reaction occurred. The ALD release was studied by UV-Vis to evaluate the filament's ability to deliver ALD. The study was done for eight hours in phosphate buffer at 37oC. According to UV-Vis analysis, the amount of ALD delivery was 1,04mg/cm of filaments, equivalent to 5.24mg of ALD/ god filaments. These results indicate that this filament is a good supplier for producing biomaterials for drug delivery using additive manufacturing, allowing the obtention of personalized devices.

Fracture toughness of Ti42Nb and Ti5553 sandwich structure produced by Laser Powder Bed Fusion

Felipe Kowaski Martins[1], Juliano Soyama[2], Rubens Caram[2]

[1]Universidade Estadual de Campinas, [2]Universidade Estadual de Campinas (*Faculdade de Engenharia Mecânica*)

e-mail: f184877@dac.unicamp.br

The aerospace industry often needs new materials with high strength and low density, but these are usually expensive and might have limitations in their applications due to low fracture toughness.[1] Thus, the aim of this study was the development of sandwich structures composed of different Ti alloys: Ti-42Nb and Ti5553 (Ti-5Al-5V-5Mo-3Cr-0.5Fe) to improve fracture toughness. This approach involved using layers of Ti42Nb with 150 μm thickness and Ti5553 with 300 μm processed by Laser Powder Bed Fusion.[2] The results indicated improvement in fracture toughness while satisfactorily maintaining the low density and with little influence of porosity due to the manufacturing process of differentlayered materials.

Gas Atomization of Fe-6.5Si Powders for Additive Manufacturing: Production and Characterization

Vitor Eduardo Pinotti[1], Mayumi Andrade Nakahashi[1], Angelo F Andreoli[1], Piter Gargarella[1]

[1]Univerdade Federal de São Carlos (*Department of Materials Engineering*)

e-mail: vitorpinotti@hotmail.com

There is a growing need for efficient and cost-effective electric motors that consume less energy [1]. Laser Powder Bed Fusion (L-PBF) has emerged as a viable alternative for processing electric steels with 6.5%wt. of silicon, as conventional techniques result in brittle behavior due to the formation of B2 and DO3 phases [1]. Gas atomization (GA) is the main method for producing metallic powders suitable for L-PBF [3]. However, powders must exhibit specific characteristics and properties, such as a Gaussian particle size distribution, spherical morphology, flowability, and high apparent density [2]. Powders of Fe-6.5Si alloy (%wt.) were characterized to validate their use in future L-PBF studies, including chemical composition, particle size distribution, morphology, flowability, apparent density, and microstructural aspects to evaluate the presence of brittle phases. Most high-strength aluminum alloys obtain this property after precipitation-hardening heat treatments, a strategy used for over 100 years [1]. The number of alloys where this strategy can be applied is limited by the low number of elements that have significant solubility in aluminum. Another possibility to strengthen aluminum alloys is by forming quasicrystalline phases [1]. Recent data have shown that it is possible to obtain a metastable quasicrystalline phase in a large volume of Al-Fe-Cr-Ti alloys manufactured by Laser Powder Bed Fusion (L-PBF) [2]. These alloys are promising in applications such as matrices and structural parts, as they have high mechanical strength, especially for applications at high temperatures. These alloys are expected to exhibit high fracture toughness due to a microstructure that combines the presence of a high-strength quasicrystalline phase in a highly refined ductile aluminum dendritic matrix due to the high cooling rates involved in the L-PBF process (10^5 K/s) [2]. The precipitation heat treatment of these Al-Fe-Cr-Ti alloys manufactured by L-PBF was not studied so far. Thus, this project consisted of carrying out a series of heat treatments of the Al95Fe2Cr2Ti1 alloy produced by L-PBF and evaluating their influence on the phase formation and mechanical properties. The results indicated an increase in hardness for certain heat treatment conditions, thus indicating that, these alloys can be applied and classified as solid solution hardened.

Tuberculosis constitutes a public health issue, particularly concerning arduous pediatric treatment. 3D printing (3DP), enables customized, palatable formulations with multiple drugs in a single medicine. Semi-Solid Extrusion prints medicines using a semi-solid intermediate production formulation [1]. The systematic approach begins with predefined objectives, utilizing the Quality by Design (QbD) principle to identify critical quality attributes (CQAs), critical process parameters (CPPs), and critical material attributes (CMAs) that affect the quality target product profile (QTPP). It helps to achieve high-qualityprototypes with reduced variability [2]. This study aims to identify the CPPs that impactsQTPP, defined as a gummy of isoniazid content for the treatment of tuberculosis, using a QbD approach. QTPP and CQAs were defined to identify the CMAs and CPPs. Potential risksimpacting QTPP during formulation and printing were identified through brainstormingusing Ishikawa cause and effect analysis. These risks were further analyzed using FailureMode and Effect Analysis (FMEA), considering Severity (S), Occurrence (O), and Detection (D) on a numerical scale (RPN = SxOxD). Finally, variables with the highest risk were selected based on high-risk attributes (RPN > 250). Risk analysis of CQAs using Ishikawa identified parameters with significant material impact. Six parameters and their independent variables were determined: Formulation, Rheology, Computational design, Printing process, pharmaceutical form and Packaging. Based on FMEA analysis, the high-risk CQAs are Print hole; Temperature; Formulation viscosity; Flow rate. With the high-risk CQAs defined, it is possible to conduct process improvement strategies to enhance the printing and medicine performance.

e-mail: antonio.jose@int.gov.br

The extrudability of an ink is composed by the flow stress and the flow behavior index. The first parameter represents the minimum shear stress required to make the ink flow, which is related to the minimum force required by the 3D-printer to extrude an ink, and the second one describes the flow behavior of the material. The shape fidelity. It is important to note that, unlike when using polymeric materials, printing is not the final step when manufacturing ceramic parts by DIW. Most ceramic inks require post-printing treatments, which involve shrinkage, very significant in the case of sintering. These dimensional changes must be taken into account when designing the CAD model of the green parts, and the shape fidelity of the green part is a crucial aspect to ensure the accuracy of the whole process.

In this study were evaluated the influence of particle , particle distribution. pH and surface area of an s alumina, zirconia and alumina-zirconia ceramics on the rheological behavior of inks employing polyvinyl alcohol and polyethilene glycol used as viscosifying and coagulant agents in deionized water. 3D printing was performed using a DURAPRINTER E02 model and was possible to obtain ceramic pieces of complex shapes with dimensional accuracy and theoretical densities up to 96%.

Additive manufacturing (AM) is a new processing technology that involves layer-by-layer construction of a part. Laser beam powder bed fusion (PBF-LB) is one of the most applied AM processing for metals. PBF-LB involves more than one hundred parameters, where the most influential are the power and speed of the energy source. In most cases, inert atmospheres are often neglected in processing optimization. The current work evaluated the influence of two process atmospheres (argon or nitrogen) in the processability of AISI 316 L stainless steel. The type of gas in the process chamber displaces the high-density conditions. Crystallographic orientation, nitrogen content, grain size distribution, and thermal properties of bulk parts were modified due to the atmosphere applied. This work was supported by CNPq, CAPES, and FAPESP.

This research used resources of the LNNano/CNPEM (SEM facilities). The authors thank Ominitek for providing access to the PBF-LB machine, Prof. Rubens Caram for providing access to the oxygen/nitrogen analyzer.

Influence of texturing parameters on surfacemodification of UNS S32101 duplex steel

e-mail: afbugarin@usp.br

The application of laser texturing aims to modify the surface without changing its chemical composition. These alterations can be evaluated through mechanical, physical or chemical tests. Texturing can be applied to improve efficiency in industrial processes, such as the flowability of materials, by applying laser texturing to the internal surfaces of components. This work aims to evaluate the influence of texturing parameters in the flow process of industrial batchers. UNS S32101 lean duplex stainless steel (LDSS) samples were used for the tests. For laser texturing of the surfaces, laser of Yb was used, with a wavelength of 1064 nm (infrared), using the scanning speed of 140 mm/s and pulse duration of 150 ns. Two sets of textured samples were produced: with a frequency of 50 kHz and 2 kHz. In both frequencys, the power(%) was set at 100, 60 and 20. The effect of texturing was analyzed through microstructural characterization with tests of contact angle, roughness and scanning electron microscopy.

Influence of the additive manufacturing parameters on the Ti6Al4V microstructure

e-mail: mq_fernanda@yahoo.com.br

The 3D printing on an industrial scale describe the one more advanced techniques. In the manufacturing process technology the model is created by successively layering material from a digital 3D model. The 3D manufacturing process allows obtaining complex geometry, weight reduction, and customized components. A careful microstructure characterization of the produced components is necessary, since the parameters influence in surface roughness, microhardness and corrosion resistance. Samples of Ti6Al4V built with the same laser speed, hatch distance and layer thickness but different laser power were analyzed. The variation in laser power influenced the roughness and corrosion resistance of the samples.

Investigaten of 316L stainless steel parts produced by Wire Arc Additive Manufacturing - WAAM

Vera Lucia Arantes[1], Francisco Maciel de Brito Neto[1], Haroldo Cavalcanti Pinto[1], Raíra Chefer Apolinario[2], Júlia Nascimento Pereira[1]

e-mail: vera@sc.usp.br

Additive manufacturing technologies have been revolutionizing the paradigm of manufacturing and engineering areas, due to the possibility of creating three-dimensional, complex and near net shape parts. Among these technologies, Wire Arc Additive Manufacturing (WAAM) is highlighted due to its high deposition rate, low equipment cost, high material usage (little waste) and consequent respect for the environment.

In this work, parts of austenitic stainless steel 316L were produced by WAAM with layer overlap angles of 45° and 90°, using values of U=21.2V, I=220A and WS=15mm/s, these welding parameters were defined in initial tests.

XRD measurements were performed along the Z axis´surface, on the samples´surface in order to evaluate the distribution of phases and residual stress by the sin2(phi) method, and the microstructure of the cross section of selected pieces were analyzed by SEM.

In initial analyses, a better surface quality of the sample was observed with an overlapping angle of 90°.

The majority phase present in the pieces is γ austenite, but δ ferrite was also observed, which was confirmed by XRD and SEM analyses. The ferrite presented vermicular, columnarand lathy morphologies in different regions of the samples in the SEM images.

In the XRD measurements, there is a great variation in the relative intensity of the peaks, mainly in those referring to the planes (111) and (200) of the austenite, indicating a high texture, which is characteristic of the materials produced by WAAM [2].

The part that was built with an overlapping angle of 90° preferably presented compressive stresses along the Z axis, with magnitudes between 100 and 200MPa.

Investigation of the influence of patterns and percentages of fills on the mechanical properties of 3Dprinted PLA

The Fusion and Deposition Modeling (FDM) technology is a manufacturing method that uses polymer/filaments as a raw material. In this technique, the filament is usually heated to its molten state and then extruded through the nozzle of the 3D printer [2]. Due to the melting and deposition of the material under the bed, there are limitations of inputs that can be employed, usually, polymers such as PLA and ABS are used as they have satisfactory thermal properties [3]. This study will investigate the influence of fill patterns (hexagonal, triangular and concentric) in the mechanical properties of PLA 3D Printed The material will be Made througg Additive Manufacturing, by The FDM technique. And, characterized by X-ray Diffraction, and by Raman spectroscopy. The mechanical tensile properties of the printed polymer shall be determined in accordance with the standard [1]. The result of the XRD characterization shows that PLA has a semicrystalline nature. With regard to Raman characterization, the results show C-O-C and CH3 vibrations at 317 cm-1, C-CO vibrations at 407 cm-1, stretching of C=O at 740 cm-1, C-COO vibrations at 872 cm-1, stretching C-H3 at 1043 cm-1, vibrations of CH3 assigned in 1128 cm-1, deformation CH in 1302 cm-1, deformation CH3 in 1383 cm-1, symmetrical deformation of CH3 at 1453 cm-1, stretching of CH/C=O at 1764 cm-1, symmetrical and asymmetric stretching of CH3 at 2878, 2948, 3004 cm-1. The mechanical characterization of traction shows a direct influence of the filling pattern on the properties of the printed parts. the concentric pattern being the best result with 41.26 MPa, the hexagonal pattern presented 28.12 MPa and, finally, the triangular filling presented a limit of 11.63 MPa.

One of the techniques used in the Additive Manufacturing processing of aluminium alloys is Powder Bed Fusion Laser Beam (PBF-LB). As a result of laser processing, the solidification conditions lead to microstructures that are far from equilibrium, exhibiting extreme microstructural refinement and high residual stresses. The cells in AlSi10Mg samples produced by PBF-LB comprise an aluminium matrix and a continuous fibrous eutectic silicon network [1,2]. Post-processing heat treatments are typically applied to specimens produced by Additive Manufacturing to modify the as-built (AB) microstructure and subsequently improve their mechanical properties [1,2,3]. In this study five different heat treatments were studied, stress relief at 300 °C for 2 h, homogenization at 540 °C for 2 h followed by artificial aging at 170 °C for 8 h, homogenization at 540 °C for 6 h followed by artificial aging at 170 °C for 14 h, direct artificial aging at 155 °C for 6 h and direct artificial aging at170 °C for 2 h. The as-build microstructure showed a typical PBF-LB cellular-dendritic solidification structure, that following direct artificial aging the silicon network undergoes partial degeneration, and the solidification structure was erased after stress relief, homogenization followed artificial aging heat treatments. The hardness value of the AB was 133,6 ± 3,9 HV, while that of the direct artificial aging treatment samples was 153,5 ± 4,2HV. On the other hand, the other heat treatments decrease the hardness compared to theAB condition.

Laser parameters, powder geometry and the influenceon roughness of Ti-13%Nb-13%Zr alloys produced by Laser Powder Bed Fusion

Jamil Martins Guimarães Junior[1], Fernando José Gomes Landgraf[2]

[1]Universidade de São Paulo (*EPUSP*) , [2]Universidade de São Paulo*e-*

mail: eng.jamiljunior@yahoo.com.br

L-PBF is capable of creating complex and customized products quickly and precisely by depositing molten powders using a laser onto layers. The Ti-13%Nb-13%Zr alloy has excellent properties in terms of corrosion resistance, low elastic modulus and high biocompatibility, making it a great possibility for applications as biomaterial. The optical perfilometry technique simultaneously illuminates the surface studied and a reference surface. When the light is reflected by both surfaces, a topographical representation is formed, characterizing the roughness of the metal surface. The morphology of the powders can be decisive during the manufacture of products by L-PBF, and for this reason, this work investigated the influence of spherical and irregular powders in the additive manufacturing of parts using different powers, since the research of low roughness can avoid later surface treatments. HDH samples showed a slight increase on the number of spatters (superficial defects) comparing to the PA samples. Nevertheless, the difference was not very significative when assumed the same laser power. A microscopic analysis shows that the metal roughness is associated to oblique lines of the surface. These lines possibly correspond to solidification fronts created during the L-PBF process. For lower laser powers, these lines can be presented as very clear "V" shapes called "ripples", pointing tothe opposite direction of the laser movement. For neighboring tracks, these ripples point toopposite directions between themselves. It´s possible to conclude that bigger laser powersresult in more parallel ripples, hiding part of themselves by the neighboring tracks. By perfilometry was possibly to infer that: A power of 200W resulted in bigger roughness whenfabricated products made of HDH powder; The lowest roughness was obtained by PA powder and 250W and it is also possible to conclude that roughness is inverselyproportional to the laser power for all samples.

Microstructural and mechanical characterization of the maraging 300-grade steel processed by additive manufacturing (L-PBF) using different powder feedstock

Gabriel Cotrim de Cesare Peinado[1], Cauê Pettermann Carvalho[1], André Luiz Jardini[2], Julián Arnaldo Ávila Diaz[3,4], Eduardo Netto de Souza[5], Carlos Antonio Reis Pereira Baptista[1]

e-mail: cotrimcesare@gmail.com

The production of parts by additive manufacturing (AM) has grown in recent years, mainly due to decreased cost and the insertion of new materials for applications taking advantage of the complex geometries that can be fabricated. Maraging steels are ferrous alloys presenting ultra-high strength. Maraging 300-grade steel with 18% nickel (18Ni300M) has been adopted for applications that demand high mechanical strength and dimensional stability, such as in the aerospace and military fields [1]. Recent works investigated the mechanical and microstructural properties of 18Ni300M steel processed by L-PBF [1]. However, studies on the particulate raw material's influence on the parts' properties are scarce [2]. The main objective of the present work is to investigate the microstructures of two feedstock powders of 18Ni300M steel (X and Y) and evaluate the mechanical properties of LPBF parts manufactured from these powders. The powder X was gas-atomized by an AM commercial provider and Y was water-atomized by a local atomization company. The material processing by L-PBF was performed at FEQ/UNICAMP. Microstructural and mechanical characterizations were conducted at EEL/USP. From the results, it was verified that particle distributions of the two feedstock powders diverged concerning the data provided by the atomization companies. In addition, powder Y presented worse morphometric parameters than powder X, which compromises the L-PBF process, as evidenced by the porosity in the built samples. Due to these defects, samples processed withbatch Y exhibited a lower mechanical response, particularly in ductility (11% for batch Xand only 4% for batch Y). Furthermore, fractographic analyses revealed defects such as pores and inclusions in both materials. However, the defects in batch Y appeared to be moresevere and could compromise the material's structural integrity.

Microstructural Characterization of the High Strength AA2017 Alloy Produced by Laser Powder Bed Fusion

Bruna Fernanda Batistão[1,2], Sergio de Traglia Amancio-Filho[1], Piter Gargarella[3] [1]Graz University of Technology (*Institute of Materials Science, Joining and Forming, BMK Endowed Professorship for Aviation*), [2]Federal University of Sao Carlos (*Graduate Program in Materials Science and Engineering*), [3]Federal University of Sao Carlos (*Graduate Program in Materials Science and Engineering; Department of Materials Engineering; Center of Characterization and Development of Materials*)

e-mail: bruna.batistao@estudante.ufscar.br

High Strength Al-Cu alloys are widely applied in the aerospace and automobile industries due to their high specific strength, and good fatigue and corrosion resistance. Nevertheless, the processing of Al-Cu alloys by Laser Powder Bed Fusion (L-PBF) remains a challenge because of their large solidification interval, which leads to hot cracking in the final piece. Based on this, the objective of this work was to process the AA2017 alloy, which is the oldest and best known alloy of the Al-Cu system, by L-PBF. Box Behnken design of experiments (DoE) and analysis of variance (ANOVA) were used to assess the influence of the processing parameters (i.e. laser power, scanning speed, and hatch distance) on residual porosity and relative density. Optical microscopy and scanning electron microscopy equipped with an energy-dispersive X-ray spectrometer were used to characterize the microstructure of the alloy processed by L-PBF. The set of process parameters optimized via DoE/ANOVA resulted in high relative density (>99%) and low residual porosity. The as-built microstructure was characterized by the typical α-Al columnar grains along the building direction and Al_2Cu precipitates. Precipitates with a concentration of Mg and Si, and Fe and Mn were also observed and identified comparing with the phases formed in the solidification of the alloy according to Thermocalc computational thermodynamics software (version 2021b), TCAL3 database, and the literature.

Modulating alginate-based hydrogels crosslink densityvia calcium ions

Viviane Fajardo Filgueiras[1,2], Paula Cristina Gomes Fernandes[3], João Henrique Lopes[3]

[1]Instituto Tecnológico de Aeronáutica, [2]Universidade Federal de São Paulo, [3]Instituto Tecnológico de Aeronáutica (*Departamento de química*)

e-mail: viviane.fajardo@unifesp.br

Hydrogels are a type of polymer-based network with ability to absorb water and other bodily fluids and capacity to mimic the extracellular matrix. Because of this unique property, hydrogels are widely used in tissue engineering through a versatile platform after rational structure and functional design that leverages on material engineering to modulate its physicochemical properties, and influence cell signaling cascades and fate [1]. Alginate is a natural polymer that has garnered significant attention due to its biocompatibility and ability to crosslink in a fast and efficient manner. One of the key advantages of alginate-based hydrogels is their ability to undergo rapid crosslinking through the attachment of carboxylic groups to a divalent metal ion during their formation. Calcium is the most commonly used metal ion for alginate gelation, as it allows for a rapid gelification and is also an essential mineral for human metabolism. However, the hydrogel resulting from this mixture is highly sensitive to the conditions under which it is prepared. Here, we investigated the effect of Ca2+ on the structural and rheological properties of alginate hydrogels, aiming to obtain gels with high homogeneity and stability. FTIR was used for the structural characterization of the hydrogels, while the water content and swelling degree of hydrogels were determined using the gravimetric method. Our findings revealed a strong influence of Ca2+ concentration and addition rate in the alginate solution, temperature, intensity and time of agitation during the crosslinking on the homogeneity and stability of the resulting hydrogel.Acknowledgments: The authors are grateful for the financial support provided by the São Paulo Research Foundation (FAPESP), through processes 2022/11767-0, 2022/07967-3, and 2022/03247-6. 3D printing technology has gained attention in the production of electrochemical (bio)sensors [1]. This expansion is due to the ability to produce devices quickly, and automated. However, there is still much to explore, especially about the main material used in conjunction with 3D printing technology, the conductive filament [1,2]. The production of conductive filaments has gained notoriety, as it allows the production of electrochemical devices. The producing lab-made conductive filaments allows the manufacture of materials with varied compositions and replaces the need to import this product [1,2]. Manufacturing lab-made conductive filaments is an excellent alternative for the production of electrochemical sensors capable. In this work, we report the development of a lab-made filament composed of carbon black and polylactic acid. Optimized filaments containing 28.5% weight of carbon black were obtained and used in the 3D printing of electrochemicalsensors by the fused deposition modeling technique. The manufactured sensors was exploited to detect catechol and hydroquinone in water samples and hydrogen peroxide inmilk. The determination of catechol and hydroquinone was successfully performed by differential pulse voltammetry, showing LOD of 0.02 and 0.2 μmol L^{-1}, respectively, and recovery values ranging from 91.1 to 112% in water. The modification of the sensor withPrussian blue allowed non-enzymatic amperometric detection of hydrogen peroxide, with alinear range between 5.0 and 350 μmol $L^{-1}$and LOD of 1.0 μmol L^{-1}. Thus, the filaments can be applied to build electrochemical sensors capable of being applied for various purposes.

e-mail: marcio.sangali@gmail.com

The demand for improved load-bearing devices for orthopedic implants has led to the development of novel Ti alloys, particularly metastable β Ti alloys. The choice for Ti alloys is justified by the exceptional corrosion properties, high biocompatibility, and unique mechanical behavior. Recently, the processing of Ti alloys has undergone significant changes due to advancements in additive manufacturing (AM) technology. One of the mostefficient additive manufacturing techniques is selective laser melting (SLM). Usually, SLMtechnology relies on processing costly pre-alloyed powders that have specific compositions,morphologies, and dimensions. The availability of these metallic powders is limited to only a few compositions, making the atomization of aparticular metallic alloy an expensive procedure. An effective approach to surpass restrictions regarding the availability of pre-alloyed powders is the use of In-situ alloying additive manufacturing. In this work, a Ti-30Nb-4Sn (wt.%) alloy was in-situ additively manufactured using different processing parameters. One of the aims of this work was to evaluate how the ranges of scanning speedand laser power, maintaining the same energy density, influence the porosity, homogeneity, and microstructure. The samples were synthesized using Ti, Nb, and Sn powders in an OmniSint-160 SLM machine. The experiments were conducted in an argon atmosphere with scanning speeds varying from 318 mm/s to 1000 mm/s, and laser power between 225 W and 394 W, while maintaining the energy density of 164 J/mm 3 . The compositional and microstructural analyses were performed using optical microscopy, scanning electron microscopy, and energy dispersive spectroscopy. Mechanical properties were evaluated by Vickers hardness tests. The results showed a high variation in the porosity and homogeneity of the samples synthesized with the same energy density, suggesting that the widely used equation does not perform satisfactorily for in-situ alloys.

Physicochemical characterization of AA2017 gas-atomized aluminum powders for its application in LPBF

Nicolas Rojas Arias[1,2], Francisco Gil Coury[3], Sergio de Traglia Amancio-Filho[4], Piter Gargarella[5]

e-mail: nicolas.rojas@estudante.ufscar.br

Laser Powder Bed Fusion (LPBF) is one of the most used techniques for the construction of metal parts by additive manufacturing. Although the physical and microstructural characteristics of the LPBF parts depend of different factors related to the characteristics of the machine and the processing parameters, the physicochemical characteristics of the raw material used also influence the quality of the built part. In this sense, the characterization and understanding of the physical, microstructural, and morphological characteristics of metal powders destined for LPBF are of great importance. Considering the above, the characterization of gas-atomized powder samples of the AA2017 aluminum alloy was carried out in this work. The particle distribution, moisture, and fluidity of the powder samples were performed by sieving, drying tests, and Hall funnel. The microstructural and morphological characteristics were performed using optical microscopy (OM) and scanning electron microscopy (SEM). Phase characterization was performed by X-ray diffraction (XRD). The results obtained in this work demonstrated the obtaining of powder samples with an optimal particle size distribution and efficiency of the atomization process greater than 90% during atomization, and obtaining 71% of useful powder to be applied within LPBF (between 20μm - 63μm, for this work). The characterization through OM and SEM allowed to observe the formation of predominantly spherical powders, presenting an ideal morphology for its application within LPBF. Nevertheless, the fluidity tests carried out using a Hall funnel did not show a good fluidity of the material. Likewise, the drying stages of the material revealed that the powder samples are prone to capture a large amount of moisture from the environment, which can negatively influence the fluidity of the material, as well as the possible formation of defects in parts built by LPBF due to the formation of oxide layers.

Preparation and characterization of nano-hydroxyapatite paste for additive manufacturing

Hydroxyapatite, a calcium phosphate-based ceramic found in bone tissue, is one of the most used ceramics to produce feed materials for 3D printing. Due to its excellent biocompatibility and biodegradability properties, it can be used in many areas, such as biomaterials and environmental applications [1]. Hydroxyapatite nanoparticles were synthesized by the sol-gel route using the sonicator technique [2]. Nano-Hydroxyapatite (nanoHAp) pastes were prepared using Poly(Vinyl Alcohol) - PVA and Poly(ethylene glycol) -PEG as organic binders. Firstly, the PVA:PEG, with a proportion of 7:3, was solubilized in distilled water under heating and vigorous stirring. The nanoHAp powder was added to the polymer-based solution at 70, 80 and 90%wt using an Ultra Turrax homogenizer for 10 min. The flowability of the pastes was evaluated by extruding tests [3] using syringes with needles of 0.84 mm in diameter at printing speeds of 5 and 120 mm/min. The microstructure and chemical composition of the nanoHAp powder and paste samples, before and after sintering at 1070 ℃ for 120 min, were evaluated by SEM/EDS and XRD analysis. The results showed that the synthesized nanoHAp powder is composed of agglomerates and particles with an average size of 1.3 ± 0.95 microns and 21.0 ± 4.9 nm, respectively. The paste with 80%wt of nanoHAp exhibited the best flow characteristic for additive manufacturing.

Laser Powder Bed Fusion (L-PBF) is a selective laser sintering technique used in Additive Manufacturing (AM) to create composite materials with a polymer matrix, including permanent magnet materials. Previous research has shown that processing parameters and feedstock characteristics can impact the properties of composite magnets [1, 2]. However, less attention has been given to the interaction between the laser beam and the magnetic particles, and its effect on the microstructure and properties of the fabricated magnet. In this study, Nd-Fe-B powders with varying particle s were mixed with polyamide-12 powder to create feedstocks for L-PBF. The L-PBF process affected the intrinsic coercivity of the powder particles differently, with smaller particles being particularly sensitive to the laser beam's interaction under atmospheric conditions. Based on these findings, an encapsulation method was developed to shield small powder particles from degradation during the L-PBF process. By utilizing this approach, PA composite magnets with particles in the 4 µm range were successfully prepared, with an intrinsic coercivity of 900 kA/m.

Aerospace components produced through Metal Additive Manufacturing (AM) have a promising future in several industry sectors. Among the AM processes, Laser Powder Bed Fusion (L-PBF) allows savings in finishing processes and enables the creation of complex geometries, in addition to enabling the topological optimization of parts, increasing component efficiency. Precipitation Hardening (PH) Stainless Steels are of great interest to the aerospace industry due to the combination of properties such as high mechanical strength, good ductility and good corrosion resistance [1]. In this work, the optimization of processing parameters of stainless steel 17-7 PH by L-PBF was studied, aiming to achieve high density and low volume of defects. The varied processing parameters were scanning speed (600, 900, 1200 mm/s) and laser power (98, 144, 186, 230 W), while layer thickness, hatching and scanning strategy were kept constant. The samples produced showed relative densities ranging from 60.5% to 99.9%. The highest densification was obtained for the parameter set that has the highest volumetric energy density. Before and after solubilization heat treatment for the sample with the highest relative density, microstructure characterization using techniques of Optical Microscopy (OM), phase quantification by X-Ray Diffraction (XRD) and Vickers microhardness have been performed. To evaluate the corrosion resistance, electrochemical measurements have been performed in 3.5% NaCl solution at 25 °C with a classic three-electrode cell configuration.

e-mail: cymorassuti@cti.gov.br

X-ray computed microtomography (μCT) is a non-destructive technique used for studying several samples. It allows for the analysis and reconstruction of three-dimensional models based on X-ray projections. However, the ideal condition for X-ray transmission is necessary for the acquisition of each projection image. The Bruker Skyscan 1272 μCT, equipped with a CMOS detector, requires a transmission value between 40 and 15% (for acquisition of ½ of revolution) [1]. In this work, we present a quick methodology to estimate the thickness of 3D-printed samples that exhibit X-ray transmission within this range. Theoretical models that predict transmission decay curves as a function of the sample's thickness were generated using the Lambert-Beer Law. We used a 3D-printed sample with different thicknesses ranging from 1.0 to 5.0 mm, and cubes (edge cubes: 5.0, 10.0, and 20.0 mm), printed in polyamide 12 employing the Selective Laser Sintering technique (SLS) in the HiQ 3D printer. We tested the methodology for all the standard filter configurations present in the Skyscan 1272 μCT. Comparing the theoretical results with the experimental ones, we observed that the models exhibit good reproducibility with recovery values between 90% and 100%. The importance to establish such protocol is the near future offer of this equipment as an open facility, complementing the current ones available at CTI Renato Archer.

Red ceramic waste reuse for application in catalytic reactions

Lís Andréia Januário de Souza[1], Aracelis José Pamphile Adrian[2], Pedro Pablo Florez Rodriguez[3], Eduardo Emanoel Batista[4]

[1]Federal University of Alagoas (*IQB*) , [2]Universidade Federal de Alagoas (*Instituto de Química e Biotecnologia*) , [3]Universidade Federal de Alagoas (*IQB*) , [4]Universidade Federal de Alagoas

e-mail: lis.souza@iqb.ufal.br

The ceramic industry is one of the fastest-growing sectors, leading to a considerable accumulation of ceramic waste[1]. Therefore, several ways to reuse these residues in different areas make it a promising material for the industrial area: catalyst, tubular ceramic membranes, etc. Thus, the research aims to study the physicochemical characteristics of catalysts supported on ceramic waste (roof tiles) for potential reuse for printing of structured catalysts by adding manufacturing [2]. After characterization of the wastes, Cu, Ni, and Fe catalysts supported on the roof tiles wastes were synthed by impregnation of nitrate salts of the metals to obtain 10wt.% Cu, Ni, and Fe catalysts, respectively. The support and catalysts were characterized through TGA/DTA, XRF, XRD, N2 physisorption, and H2-TPR. EDX characterization of the tile waste showed the presence of Si, Fe, Al, K, and Ti was observed, with Si being the most abundant in the SiO2 quartz phase, according to XRD analysis. This phase was also found in XRD analysis of the prepared catalysts, besides the characteristic peaks of Cu, Ni, and Fe. TPR profiles of catalysts showed high reducibility at temperatures lower than 600 °C, representing an advantage for industrial applications. The Ni/T C catalyst showed a single consumption of H2 in its TPR profile, with a maximum at 456°C. Two peaks were found in Cu/T, at 344°Cand 454°C, attributed to CuO reduction in two stages. For Fe/T, a two-step reduction wasalso observed, with peaks at 333°C and 440°C. Printing tests, model catalytic and glycerol conversion reactions are under development to study these properties' effect on the catalysts' activity and selectivity.

e-mail: caio.c.santos@unesp.br

The cement industries are among the most important of carbon emissions. As a result, researchers and industry experts are increasingly seeking eco-efficient materials that can improve the sustainability of cement production. One promising approach is using nanostructured additives in cement pastes [1]. Recently, the memory effect of mixed oxide (MO) derived from the calcination of layered double hydroxides (LDH) was used to improve the properties of cementitious materials [2]. This study used LDH based on Mg0,66Al033(OH)2(NO3)0,32·xH2O to prepare MO additives. The impact of specific surface areas (SSA) and the amount of MO additives on the rheological properties of Portland cement pastes was investigated. LDH with different crystallinity was used to obtain MO additives with SSA= 220, 176, 98, and 53 m2 g-1. The results indicate that both parameters (quantity and SSA) influence the character of cementitious materials. The flow tests evidenced a significant shear stress reduction in the paste containing 1 wt% of MO additive. In contrast, the shear stress was increased by the addition of 2 and 3% of MO on the paste. When both parameters are raised, the consolidation time of the pastes is clearly reduced. The additives altered the hydration reactions of the cement paste, which led to a decrease in the pores volume of the cement. The cement additives affected rheology and porosity over time, and this information was used to build a response model. Therefore, the research involving the addition of MO to cement could enhance cement industry sustainability.

Several industrial reactions use catalysts with specific functionalities. Alkaline earth metal oxides are suitable basic catalysts; however, they present disadvantages such as low specific area, low stability, and deactivation[1]. In this work, CaO was modified with Al_2O_3 in molar ratios Al_2O_3/CaO=0.5; 1 and 2 to study the effect of molar ratio on the physicochemical characteristics of solids, emphasizing on acid-base properties, for potential for printing structured catalysts by adding manufacturing[2]. The mixed oxides were synthed by co-precipitation from $Al(NO_3)_3 \cdot 9H_2O$, CaO (produced from egg shells) and NH_4OH. Subsequently, the supports were impregnated with 10wt.%Cu, obtaining Cu/CA0.5, Cu/CA1, and Cu/CA2. The supports and catalysts were characterized by TGA, DRX, EDX, TPD-NH_3, TPD-CO_2, TPR, and N_2 physisorption. XRD diffractograms of the supports showed crystalline phases that differed between the materials, showing that the morphology changed given the molar ratios. TPD-CO_2 profiles showed that the CA2 support mainly presented weak basic sites, while the CA1 and CA0.5 presented a heterogeneous distribution with medium and strong basic sites. TPD-NH_3 profiles showed an opposite trend for acid sites. Thus, it's noted that the difference in molar ratio modified the solid's crystalline structures, altering the acid-base properties. On the other hand, copper catalysts showed CuO reduction peaks with different metal-support interactions. Printing tests, model catalytic and glycerol conversion reactions are under development to study these properties' effect on the catalysts' activity and selectivity.

Metal oxides are widely used in catalytic reactions due to their physicochemical properties. CaO has been used in several reactions that occur through a basic mechanism[1]. Despite its low cost and accessibility, it has disadvantages such as leaching and low specific area. In this work, CaO was modified with Fe_2O_3 in molar ratios Fe_2O_3/CaO=0.5, 1.0 and 2 to study the effect of molar ratio on the physicochemical characteristics of solids, emphasizing on acid-base properties, for potential for printing structured catalysts by adding manufacturing[2]. The solids were obtained by co-precipitation of Fe(NO3)3·9H2O with the proper amounts of CaO, obtaining CF-0.5, CF-1.0 and CF-2.0. After calcination, the solids were impregnated with copper nitrate to obtain 10wt.% Cu catalysts supported on mixed oxides. The solids were characterized by the techniques of XRD, NH_3-TPD and CO_2-TPD. This work achieved good results regarding the formation of mixed crystalline phases identified by XRD, obtaining phases of pure iron oxides, Fe_2O_3, and mixed phases, with different concentrations for the solids. TPD-CO_2 and TPD-NH_3 profiles, showed differences in the distribution of acid and basic sites in the synthed solids. For the TPD-CO_2 analyses, itwas possible to identify the presence of weak and strong basic sites, where with the lowestmolar ratio there was greater CO2 desorption. For the characterization of TPD-NH_3, the opposite was observed regarding the distribution of basic sites, acid sites were more expressive when the Fe_2O_3/CaO molar ratio increased. Printing tests, model catalytic and glycerol conversion reactions are under development to study these properties' effect on thecatalysts' activity and selectivity.

e-mail: jonas.alcantara@iqb.ufal.br

Precious metal-based catalysts are widely used due to their catalytic activity[1]. However, the use of nickel as a catalyst is receiving increasing attention due to its low cost and catalytic activity, similar to precious metals. The present work studied the effect of the reaction parameters in obtaining nickel nanorods. The synthesis was developed by modifying the method proposed by LUO, Y. et al.[2]. Three different precursors $NiC2O4·2H2O$, $NiCO3$ and $Ni(NO3)2·6H2O$, pH between 8 and 14, reaction temperatures between 100 and 180°C and reaction time between 24 and 110 h were used. All syntheses were performed in an autoclave reactor with a teflon coating. The solids were purified by centrifugation at 3000 RPM for 10 min, dried at 80°C for 24 h, and posteriorly characterizedby XRD, SEM, and H2-TPR. The XRD analysis showed that when nitrate and carbonate precursors were used, a crystalline structure of $Ni(OH)2$ was obtained. For the oxalate precursor, it was possible to obtain the crystalline phase of nickel oxalate. Scanning Electron Microscopy showed that nickel rods were only obtained when using Nickel Oxalate, when modifying the synthesis temperature, and different widths when modifying pH. The synthesis time did not show significant differences in the morphology of the rods, but the XRD showed a better crystallinity for the solids synthed in 132 h. The temperature-programmed reduction of the obtained rods showed a reduction peak at 380°C. The best synthesis conditions to obtain rods with uniform diameter distribution and high crystallinity were 180°C, 24 h, and pH=14.

The influence of print orientation in the production of porcelain pieces through Direct Ink Writing

Gabriela Machado Guimarães Ferreira[1], Sebastião Ribeiro[1]

[1]Escola de Engenharia de Lorena - Universidade de São Paulo (*Departamento de engenharia de materiais*)

e-mail: gabriela_guimaraes@usp.br

Porcelain has physical characteristics that allow its use in different fields of application, ranging from domestic to industrial. However, the disadvantage is the difficulty of producing complex and detailed geometries. Direct Ink Writing (DIW) is an additive manufacturing technique that uses material extrusion to manufacture 3D structures, allowing the production of customized parts quickly and without material waste [1,2]. In this context, it is important to understand the influence of the layers'' orientation of samples produced using robocasting on their mechanical properties. The products will be developed using the DIW of ceramic materials, being block and cubic specimens. For printing the specimens, three different orientations will be considered, and sintered at 1250ºC for 2 hours. SEM will be used to evaluate the morphological characteristics of the material. The determination of the mechanical characteristics of the material will be done through axial compression and three-point bending tests. In this way, the work seeks to understand the behavior of parts manufactured through DIW regarding the orientation of the layers and the influence of the production of the final properties of the material.

e-mail: vanessa.batista@sc.senai.br

Laser Powder Bed Fusion (L-PBF) is the metallic Additive Manufacturing (AM) technology with the highest worldwide adoption level by industry. Among the advantages of this technology concerning others, we can mention the selectivity and the possibility of building impossible geometries [1]. Selectivity is directly related to the thermal history and processing parameters that will determine how printable a given powder is and the material properties at the end of manufacture [2]. This investigation aimed to evaluate the effects of main L-PBF parameters on the properties of the 316L stainless steel alloy, one of the most applied materials in the industry: density, hardness, microstructure, and phase composition. A single laser L-PBF machine was used to process cubes with a side of 10 mm using the same gas-atomized powder (with 20 and 53 micrometers in volume, D10 and D90, respectively) and with a layer thickness of 0,060 mm. There were variations of two laser scanning strategies (Continuos and Chess), three power levels (250, 325, and 400 W), three speeds (900, 1100, and 1300 mm/s) and three hatch distances (0.075, 0.105, and 0.135 mm), totalling 54 sets of parameters. The samples were characterized by Image (by Optical Microscopy) and Arquimide´s Densities, Hardness, Microstructure, and Phase Composition (XRD). Significant effects of power, speed, hatch distance and scanning strategy parameters were observed on density and hardness properties. However, no significant effects were observed on the phase compositions of the four set parameters evaluated to compare the two scanning strategies.

Thermomechanical response of 3D Porous Carbon-based Schwarzite Structures

Maria Julia Wegher[1,2], Cristiano Francisco Woellner[2]

[1]Instituto Federal de Educação, Ciência e Tecnologia do Paraná (*Curso Técnico em Petróleo e Gás*), [2]Universidade Federal do Paraná (*Física*)

e-mail: mariajuliawegher@gmail.com

Schwarzites are crystalline, 3D porous structures with stable negative curvature formed of sp2-hybridized carbon atoms [1]. These structures present topologies with tunable porous size and shape with unusual mechanical properties [2,3]. In this work, we have investigated the thermomechanical behavior under compressive/tensile strains and energy absorption of four P8-family schwarzite structures, through reactive molecular dynamics simulations, using the ReaxFF force field as available in the LAMMPS code. Our results show that under mechanical compression these structures can be reduced up to 80% of their original size before structural failure (fracture) occurs depending on the size of the "graphene patches" in the structures. Our results also show remarkable resilience under mechanical compression and high temperatures (up to 1000 K). We will also discuss recent efforts to synthesize them. REFERENCES: [1] A. L. Ultrasonic tomography to identify the presence of pipesin concrete structures

Joaquim Teixeira de Assis[1], Laio Andrade Sacramento[2], José Renato de Castro Pessôa[3], Dany Sanchez Dominguez[4], Joel Sanchez Dominguez[1]

[1]Universidade do Estado do Rio de Janeiro (*Engenharia Mecânica e Energia*) , [2]Universidade do Estado do Rio de Janeiro (*Modelagem Computacional*) , [3]Universidade Estadual de Santa Cruz (*Materiais*) , [4]Universidade Estadual de Santa Cruz (*Modelagem Computacional*)

e-mail: joaquim@iprj.uerj.br

Ultrasonic tomography as a non-destructive evaluation method has been increasingly studied in civil engineering since it has the potential of analyzing the interior of concrete structures without damaging them. Special attention has been given to the identification of water and sewer PVC pipes integrated into the structural elements since their presence can interfere with their performance. This work presents a non-destructive method for identifying the presence of PVC pipes in concrete structures using ultrasonic tomography. This technique utilizes ultrasonic waves to generate a sectional image of the concrete structure and detect anomalies. A tomographic reconstruction algorithm based on the Random transform was developed. To validate the proposed method, concrete specimens with known internal flaws were created. PVC pipes with different cross sections were located inside the specimens. Ultrasonic readings were conducted in the specimens, and tomographic images were developed. The accuracy of the images and mesh dependency were also evaluated. Experimental results demonstrate that the proposed technique could accurately identify the location and presence of pipes in the concrete specimens. The presented method could be beneficial for inspecting concrete structures for preventive maintenance and repairing concrete structures with the presence of pipes.

Valorization of Agave Americana fiber-reinforced poly(lactic) acid biocomposites for 3D printing by FDM

e-mail: thalita.neto@discentes.fat.uerj.br

Additive manufacturing (AM) of eco-friendly bio-composites had been growing recently to valorize agricultural waste and obtain green fillers capable of reducing bioplastic costs, without compromising the material processability and performance. In this study, a thermokinetic mixer processed the Polylactic Acid (PLA)/ fibers from Agave Americana (AA) (10% wt.) biocomposites to obtain 3D printing filaments extruded at 180 °C, which were used to print testing samples using Fused deposition modeling (FDM) 3D printer. Filamentswere characterized by Scanning Electron Microscopy (SEM), Thermogravimetry (TGA), Infrared Spectroscopy (FTIR), and Shore Hardness. Filaments revealed homogeneous diameters. The addition of 10% wt. fiber did not significantly influence the filament's diameter and density compared to pure PLA. On the other hand, thermal stability and morphological analysis were influenced by the addition of fiber in the matrix. Also, insertingfibers were uniformly distributed and embedded throughout the wire cross-section compared to the pure PLA due to good interfacial bonding. The composites developed haveshown enhancement in their mechanical properties (shore hardness). Despite the low concentration of natural fiber on the composites investigated in this work, the successfulobtainment of PLA reinforced with biodegradable natural fiber, compromising neither its thermal properties nor its processability and printability, opens the possibility for future work investigation into a composite with larger fiber content.

Wear and corrosion behavior of a boron-modified duplex stainless steel produced by laser powder bedfusion

Brenda Juliet Martins Freitas[1,2], Guilherme Yuuki Koga[1], Luana Cristina Miguel Rodrigues[1], Walter José Botta Filho[1], Sergio de Traglia Amancio-Filho[2], Claudemiro Bolfarini[1]

[1]Univerdade Federal de São Carlos, [2]Graz University of Technology

e-mail: brenda@ppgcem.ufscar.br

Metallic components used in the oil and gas industry are often subjected to severe corrosion and wear degradation. Most of these parts are made of stainless steels, which present high corrosion resistance but relative low wear resistance [1]. Several studies have been developing strategies to improve the wear resistance of stainless steels, such as the addition of high boron content (0.3-2 wt.%), which is responsible for the improvement of the wear resistance due to the formation of hard particles of borides [2, 3]. The production of duplex stainless steels by laser powder bed fusion (LPBF) has earned considerable interest owning to the capability to produce in a noticeably short time near-net-shape components with complex geometries. For the first time, a duplex stainless steel modified with 0.3 and 0.6 wt.% of boron was produced by LPBF and its microstructure (Scanning electron microscospy/EDX), corrosion (Cyclic potentiodynamic polarization, and electrochemical impedance spectroscopy), hardness (Vickers) and wear (reciprocating pin-on-plate test) behavior were evaluated and compared to a commercial duplex stainless steel. The 3D-printed samples present high density, a refined microstructure and the hardness increases by increasing the boron content. Capacitive field-effect sensors for biosensoricapplications

Michael Josef Schöning[1]

[1]INB (*Institute of Nano- and Biotechnologies*)

e-mail: schoening@fh-aachen.de

Among the multitude of concepts and different types of chemical sensors and biosensors discussed in literature, the strategy to integrate chemical or biological recognition elements together with semiconductor-type field-effect devices is one of the most attractive approaches. In this context, typical examples are represented by the capacitive EIS (electrolyte-insulator-semiconductor) sensor, the LAPS (light-addressable potentiometric sensor) or the ISFET (ion-sensitive field-effect transistor).These different kinds of devices are currently being the basic structural element in a new generation of chemical and biological microsensors, fabricated by means of silicon planar technology. Moreover, they provide a lot of potential advantages over conventional approaches such as the small size and weight, the fast response time, the possibility of an on-chip integration of sensor arrays, the high robustness, the possibility of low-cost fabrication, etc. At the same time, their possible field of application reaches from medicine, biotechnology, process control and environmental monitoring through food and drug industries up to defense and security requirements.This paper gives an overview on recent examples of silicon-based field-effect (bio-)chemical sensors developed at the Institute of Nano- and Biotechnologies. The sensors have been dealing with different receptor molecules such as enzymes, polyelectrolytes or DNA molecules, respectively, as well as device concepts up to biomolecular logic gates. Additionally, various immobilization strategies will be presented and discussed.

Femtosecond-laser processing of diamond for photonic applications

Cleber Renato Mendonca[1], Filipe Assis Couto[2,1], Lucas Konaka Nolasco[1], Juliana Mara Pinto de Almeida[3], Charlie Oncebay[4], Sérgio Ricardo Muniz[1]

e-mail: crmendon@ifsc.usp.br

The integration of devices suited for applications in photonics and quantum information technologies demands the development of platforms that combine, in the same structure, resonators, waveguides, and materials with desirable features. Diamond has generated interest as a material to be incorporated in such devices because defects in its crystalline structure may present phenomena of interest in the quantum information field as well as photonics. One of the most promising solid-state optically active spin systems is the nitrogen-vacancy (NV) center in diamond, which is usually produced by irradiating ultrapure synthetic diamond with beams of electrons or nitrogen ions. NV centers can be optically initialized in a well-defined quantum state, presenting long coherence times at room temperature and allowing creating protocols to manipulate its spin-state using a combination of optical and magnetic resonance techniques. NV centers can also be used as quantum sensors to detect physical parameters, such as temperature, magnetic and electric fields. Also, NV centers in diamonds have emerged as a promising platform for integrated photonic circuits, combining their nonlinear optical properties with excellent thermal properties. The controlled production/placement of NV centers in optical structures is of foremost importance, because the ability to engineer such devices can be widely used in quantum optics, photonics, magnetometry, thermometry, etc. In this direction, this work demonstrates the use of fs-laser pulses not only to generate active and spatially localized NV centers in diamond, but also to fabricate polymeric optical microcavities incorporated with nanodiamonts containing NV centers, that support whispering gallery modes (WGM). We also determined the damage threshold fluence for the diamond surface at distinct wavelengths and the influence of the number of pulses on the center generation.

Meniscus-Guided Coating of Organic Semiconductorsfor Applications in Field-Effect Transistors

Wojciech Pisula[1,2]

[1]Technical University of Lodz (*Department of Molecular Physics*), [2]Max Planck Institute for Polymer Research

e-mail: pisula@mpip-mainz.mpg.de

Solution processable organic semiconductors are promising for large area, lightweight, and flexible field-effect transistors. Control over their film microstructure and molecular organization is crucial for the charge carrier transport in transistors. Meniscus-guided coating (MGC) covers techniques like zone-casting, dip-coating, and solution shearing, and is an efficient approach to solution process semiconductors into highly ordered thin films. Over the recent years, various MGC methods have been developed to precisely tune the crystallization of semiconducting small molecules and polymers to further improve their charge carrier transport. MGC is classified into two deposition regimes, evaporation and Landau-Levich, with a transition region as mixed regime according to the relation between coating speed and the film thickness. During processing, the evaporation rate and coating speed play a significant role on the crystal growth of the molecules. Mixed solvents also permit tuning their solubility, nucleation rate and crystallization. The wettability and surface energy of the substrate also influence the nucleation and crystal growth of the organic semiconductors during meniscus-guided coating. This presentation discusses the crystallization and film growth mechanism of organic semiconductors during meniscus-guided coating that is essential for the thin film deposition for field-effect transistors. An understanding on the alignment mechanism and fundamental principles of the fluid mechanics for the crystal growth has been developed. Relations between meniscus shape, fluid mechanical process and semiconductor crystallization during solution processing are provided. Homogeneous mono- and multilayers based on conjugated polymers and small molecules have been fabricated for transistor applications through a careful control of the processing conditions.

This work was supported by the National Science Centre, Poland, through the grant UMO-2019/33/B/ST3/1550.

Solid state solvation: matrix effects in TAD-OLED

Anna Painelli[1]

[1]University of Parma (*Department of Chemistry, Life Science and Environmental Sustainability*)

e-mail: anna.painelli@unipr.it

Dyes of interest for advanced in OLED and OPV applications are extremely sensitive to the dielectric properties of the local environment. Solid state solvation plays a major role in this context and must be understood and fully exploited in the concurrent optimization of the dye inside the host matrix towards optimized devices. Here we present a joint experimental and theoretical work that sheds light on the dielectric response and relaxation of organic matrices of interest for TADF-OLED application.

Spin recombination statistics limits the internal quantum efficiency of organic light-emitting diodes (OLED) to a disappointing 25%. TADF beats the efficiency limit in purely organic systems, towards low-cost and easy to recycle devices. In TADF-OLED, non-emissive triplet states, generated upon charge injection, are converted into emissive singlets via reverse intersystem crossing (RISC).The dielectric response of the matrix and its rigidity largely and non-trivially affect the TADF photophysics. This intricate problem is faced focusing on a prototypical TADF dye, described by an essential state model, parametrized ab initio and validated against spectroscopic data in solution [1]. On this basis, we propose an original approach to address RISC rates fully accounting for the non-adiabatic coupling between electrons and conformational degrees of freedom [2] and finally to address the delicate issue of the TADF photophysics in non-polar and polar matrices [3].

Analytical Approach for the Analysis of Multivariate Impedance Data

Lucas Fugikawa-Santos[1], João Paulo Braga[2,3], Vinicius Martins de Oliveira[3], Vitor Barbanti Pereira Leite[2]

[1]Universidade Estadual Paulista (*Depto. de Física - Rio Claro*) , [2]Universidade Estadual Paulista, [3]University of Maryland

e-mail: lucas.fugikawa@unesp.br

Functionalized sensor arrays are widely used in electronic tongue/nose systems to detect and sense chemical compounds. These arrays generate multivariate complex impedance data, which are analyzed based on the global selectivity principle to qualitatively discriminate substances and their corresponding concentrations. However, commonly used analytic methods such as principal component analysis (PCA) and interactive document map (IDMAP) are non-quantitative, making it impossible to develop calibratable devices. To address this issue, we propose a novel approach for analyzing multivariate impedance data from sensor arrays used in electronic tongue devices. Our method allows for the representation of data in a quantitative 2-D space, where devices produced using similar fabrication parameters exhibit similar values when exposed to the same compound at the same concentration. To demonstrate the effectiveness of this approach, we conducted an extensive set of experiments involving the impedance (capacitance) vs. frequency spectra from 8 different types of electrodes functionalized with organic semiconducting films and 5 types of analytes at different concentrations. We also tested triplicated devices to confirm the reproducibility of the electrical impedance response. Our approach successfully discriminated between different analytes using unspecific electrodes for detection, with good reproducibility of the response. Additionally, the concentration dependence of the electrode array response allowed us to determine the detection limit for each compound and each detection calibration curve. This method can be easily extended to smart sensing applications, including biosensors, that require reliable and quantitative analysis. Acknowledgement Fapesp process 2019/08019-9.

Changes observed on performance and parameters extracted from electrolyte-gated transistors dependenton gate voltage

e-mail: keliseidel@utfpr.edu.br

Electrolyte-gated transistors (EGTs) have in their structure a dielectric electrolytic layer. Many of these electrolytes depict biocompatibility bringing the versatility of applying them as e.g.: neuromorphic devices, basic building blocks in bioelectronics or biosensors. Their electrical characterization depends on appropriate models to correctly extract the parameters. In this work, we depicted a sequence of measurements performed on EGTs operating as EGOFET and OECT from two distinguished EGTs, whose electrolyte is composed by: (i) Ion gel (P(VDF-HFP) and [EMIM][TFSI]) analyzed under different gate voltage range and different sweeping time during the scan measurement (ii) Hydrated gelatin used as a platform to add E. coli bacteria in an EGT-sensor, whose signal was quantified by the transistor' s extracted parameters. The experimental results obtained from these different devices are analyzed using two different models. Despite the major differences between devices and modes of operation, the OFET model is still largely used in literature to extract EGOFET parameters and often showing to be a misappropriated model for this transistor class. An possible alternative is the LS model which brings information about some extracted parameters dependence with $V_G$for EGOFETs and OECTs, not considered in the OFET model. This model also indicates some microscopic phenomena as, e.g. most likely region for ion diffusion into the transistor' s channel. The LS model brings a new point of view for the extraction of some parameters, a situation of extreme importance for the correct quantification/interpretation of experimental data, here quantified on two applications: a solid ion gel-EGT and an EGT-sensor.

Conformation of polyethyleneimine (PEI) interlayers used in organic electronics probed by SFG vibrational spectroscopy

Claudia Santana Gonçalves Ferreira[1], Florian Steffen Günther[2], Paulo Barbeitas Miranda[3]

[1]Universidade de São Paulo (*EESC*) , [2]Universidade Estadual Paulista (*Departamento de Física, Instituto de Geociências e Ciências Exatas, Câmpus de Rio Claro*) , [3]Universidade de São Paulo (*IFSC*)

e-mail: claudia.santana.ferreira@usp.br

Polyethyleneimine (PEI) is a versatile cationic polyelectrolyte that is a surface modifier widely used as an interlayer in organic electronics. Ultrathin layers of PEI on electrodeslead to the formation of interfacial dipoles that result in a reduced work function (WF) andtherefore could improve charge injection and device efficiency. There are two possible explanations for such WF changes: (i) the preferential ordering of polar groups at the interface and (ii) the interfacial charge transfer from the conductor to the organic semiconductor. However, a detailed experimental evaluation of the nature of this dipole layer has not yet been reported. Here we used sum-frequency generation (SFG) vibrationalspectroscopy - a non-linear optical technique intrinsically specific to interfaces and sensitiveto the orientation of polar groups - to investigate the conformational organization of PEIultrathin layers. We have studied films fabricated by dip-coating from aqueous solution andby spin-coating from isopropanol solution onto gold films, and for comparison, we also probed the organization of PEI deposited on glass, which is a non-conductive material. Theinfluence of the dip-coating solution pH on the PEI interfacial organization was also investigated. The obtained SFG vibrational spectra indicate the existence of conformationalordering at all interfaces, but only after several days after PEI deposition. This is likely aresult of a slow drying of the deposited layer. The spectra are more intense (more orienteddipoles) for dip-coated films that were fabricated from solutions with pH ~ 5 for glass andpH ~ 2 for gold, while spin-coated films tend to have less conformational order. These results are consistent with the mechanism for WF change based on molecular dipole orientation, rather than interfacial charge transfer.

Designing emitters bases on Cu(I) complexes with thermally activated delayed fluorescence and phosphorescence

Giliandro Farias[1], Cristian Momoli Salla[2], Ivan H. Bechtold[2]

[1]Instituto de Física/USP, [2]Universidade Federal de Santa Catarina (*Física*)

e-mail: giliandro.farias@hotmail.com

Speeding up the emission lifetime in luminescent copper(I) complexes has been highly challenging due to the copper atom''s relatively low spin-orbit coupling constant compared to heavier metals such as Iridium. We recently reported a [Cu(NN)(PP)]+ complex with 1,10-phenanthroline-derived containing the selenodiazole moiety, which showed thermally activated delayed fluorescence. Interestingly, this complex did not show the expected "heavy atom effect, enhancing the spin-orbit coupling matrix elements. Nevertheless, theaddition of the heavier chalcogens contributed to reducing the photoluminescence lifetimeto roughly 800 ns, which is the lowest reported so far for such [Cu(NN)(PP)]+ materials [1].This also enhanced the performance of solution processed OLEDs [2]. Moreover, the copper-iodide (Cu-I) moiety''s effect on the phosphorescence decay pathway was investigated. Temperature-dependent photophysical studies revealed a combined thermally activated delayed fluorescence and phosphorescence emission, with a phosphorescence decay rate inthe order of 104 s-1, which is higher than usual for copper(I) complexes. Density functionaltheory calculations indicated very high spin-orbit coupling matrix elements between the low-lying states of these Cu-I complexes comparable to the extensively applied coordinationcomplexes based on heavier metals. The Cu-I demonstrated to be a versatile moiety to speedup the phosphorescence decay pathway in about one order of magnitude [3]. Blue emittersbased on copper(I) complexes were also synthed, combining high emission efficiency, shortlifetime, and easy synthesis.

Direct Laser Writing Fabrication and Thermo-Optic Characterization of Polymeric Microresonators

Gabriel Henrique Armando Jorge[1], Filipe Assis Couto[2], Cleber Renato Mendonca[3]

[1]Escola de engenharia de São Carlos - Universidade de São Paulo (*Programa de pós-graduação em Ciências e Engenharia de Materiais*) , [2]Universidade de São Paulo (*Dept. of Materials Engineering*) , [3]Universidade de São Paulo (*IFSC*)

e-mail: gabriel.henrique.jorge@usp.br

Polymeric photonic devices have gained great scientific and technological interest due to their ease of processing and functionalization. Here, we focus on fabricating high-quality polymeric Whispering Gallery Mode (WGM) resonators using the two-photon polymerization (2PP) technique. WGM resonators are of great interest in optical sensing and filtering applications due to their high-Q factors and compact size. We used a Ti:Sapphire laser centered at 780 nm with a 50 nm bandwidth, 86 MHz repetition rate, and 100 fs pulses to fabricate WGM resonators doped with the azoaromatic compound DR13. The resulting microstructures were of high quality, with good structural integrity and low roughness on the walls. Taper fibers were produced for coupling light into these structures, and then the coupling to doped WGM microresonators was made. The spectra of the resonators showed high-Q factors. The effects of doping the structures with the organic DR13 compound for absorbing irradiation were also verified. When the doped structures were irradiated using a 532 nm laser, a significant modal shift was observed. Additional studies are being performed to determine which heating factor is dominant: (I) changing of the material density, and consequently its refraction index, or (II) expansion of the resonator, or even both. A direct analysis by changing the temperature of the substrate is being performed to establish a relationship between laser power and effective heating of the resonators. Also, we are performing thermal and thermomechanical analysis, respectively, to determine the transition temperatures and the polymer thermal expansion coefficient. In summary, we demonstrate successful fabrication of high-quality polymeric WGM resonators using 2PP and investigate the influence of thermal and expansion effects on the modal distribution of the structures. Our work has potential applications in basic science and in optical data transmission and microbiology sensors technologies.

Electronic Transport in Organic Solar Cells: J-VAnalytical Models and Electric Transient Measurements

e-mail: faria@ifsc.usp.br

The three current types of third photovoltaic generation - organic, perovskites, and quantum dots - are promising technologies for the production of clean and renewable energy in the near future. This presentation is devotes to bulk-heterojunction organic solar cells (BHJ- OSCs), in which the active layer is thin film of a nanostructured morphology, formed by electron donor and electron acceptor molecules. The enormous area of contact between thedonor and acceptor phases considerably increases the generation of carriers available forelectrical conduction, but, at the same time, it also enhances the probability ofrecombination between positive and negative photocarriers. Carrier recombination is one ofthe main factors limiting the efficiency of BHJ-OSCs. The classic stationary J-V (voltage- current) characterization provides us with the necessary parameters to calculate cell efficiency (short-circuit current Jsc, open-circuit voltage Voc, and fill factor FF), but offerslittle information about the mechanisms of generation and transport of carriers. Therefore,the elaboration of models and the search for alternative and complementary experimentsare necessary. In this sense, we present two J-V analytical models, one considering first-order recombination kinetics [1], and another second-order kinetics [2]. A new characterization technique will also be discussed: transient measurements [3]. To analyze the results, we use classic BHJ-type cells: ITO/PEDOT:PSS/P3HT-Th:PC61BM/Ca/Al and ITO/PEDOT:PSS/PTB7-Th:PC71BM/Ca/Al. Enhancement of NLO response of organic chromophores through solvent effects: Theoretical Modeling using a multiscale methodology

Vinícius Manzoni[1]

[1]Universidade Federal de Alagoas (*Instituto de Física*)

e-mail: vmanzoni@fis.ufal.br

Theoretical Modeling of new materials with higher nonlinear optical (NLO) activity is an important goal in photonics and optoelectronics. In particular, a challenge in Photonics and Optoelectronics is to take advantage of specific environmental forces to enhance the nonlinear optical response of π-organic materials. Under this statement, we present a systematic study using multiscale methods [1, 2], combining classical simulations and Quantum mechanical calculations to describe the substitutional effect of some chemical groups and the solvent effects on the linear and NLO properties of a series of organic compounds that should have promising uses as organic light-emitting diodes. The results reveal that the environment can also be used to tune a chromophore's optical response, leading to an enhancement of up to 10 times the NLO response of the molecule. Such studies can help in the selection of potential candidates for NLO applications, providing a valuable contribution to the development of more efficient and sustainable optoelectronic materials.

Exploring Homotruxene derivatives as potential liquid crystal anisotropic emitters with delayed fluorescence

Gustavo Sérgio dos Santos[1], Eduard Westphal[2], Ivan H. Bechtold[3], Harald Bock[4]

[1]Universidade Federal de Santa Catarina (*Chemistry*) , [2]Universidade Federal de Santa Catarina (*Chemistry Department*) , [3]Universidade Federal de Santa Catarina (*Física*) , [4]Centre de Recherche Paul-Pascal

e-mail: gustavosergiodossantos@gmail.com

The combination of blue delayed fluorescence (DF) and mesomorphic characteristics, such as presented by liquid crystals (LC), is highly interesting in the development of new organic light emitting diodes (OLEDs), because a LC can be aligned and this results in a luminescence external quantum efficiency (EQE) enhancement, along with a simplification of the device [1,2]. In this perspective, this work aims to incorporate the properties of LCs in homotruxene (HTX), while preserving the distinctive DF features of this highly promising polycyclic aromatic hydrocarbon [3]. It was observed that some compounds synthed so far present a behavior that resembles that of an LC, but that the data are so far not completely understood because of the low phase transition temperatures. However, X-ray diffraction technique at different temperatures are being carried out to better investigate the mesomorphic behavior. Time-resolved emission spectroscopic analyses (TRS) at 90 K and at room temperature show that in solution some of these materials exhibit DF (418nm or 3.0 eV) and phosphorescence (600 nm or 2.1 eV) at room temperature. The results suggest that although the characteristics necessary for a good DF are opposite to those necessary for mesomorphism, the structural proposals presented here, derived from HTX, are on the way to the simultaneous stabilization of both. In a second phase of this project, new compounds containing perfluorinated chains are being synthed. The idea is that this will both hinder non-radiative relaxation paths and favor nanosegregation of the different molecular sections, which is necessary for good DF and LCs properties, respectively.

The integration of distinct (nano)materials is attractive for the study and development of new devices with improved properties. In this sense, carbon and metal oxide-based materials have been investigated due to their potential for several technological applications, including energy storage and (bio)sensing [1-3]. Here we present the fabrication of Layer-by-Layer (LbL) and Langmuir-Blodgett (LB) films consisting of different arrangements of graphene oxide with metal oxide nanoparticles incorporated in electrodes to create suitable interfaces capable of acting in supercapacitors and (bio)sensors devices. The use of different metal oxide nanostructures (e.g. MnO_2 and ZnO) and how they were prepared and embedded into graphene sheets and combined with polyelectrolytes to form LbL films or phospholipids to form LB films will be presented, in addition to details of film fabrication and characterization methods. The supercapacitor approaches will be focused on the modification of conductive electrodes, while the sensor studies will be related to the preparation of sensing units in field effect devices. Moreover, the benefits of the arrangement of graphene oxide and metallic oxides in LbL or LB fashion films will be presented, as well as their potential properties to be explored as supercapacitors or (bio)sensors devices.

e-mail: giovanni_romeu@hotmail.com.br

Memristors are a rapidly emerging technology for information storage and processing devices. Unlike other electronic components such as resistors, capacitors, and inductors, memristors can remember the amount of charge that has previously flowed through them. This means that they can be used for information storage and processing, making them useful for a wide range of applications, from computer memory to artificial intelligence. Memristors have the potential to be smaller and more energy-efficient than traditional electronic components. This is because they can be made using nanoscale materials, and they don't require a constant supply of power to maintain their state. In this context, Graphene oxide is a promising material for developing organic memristors due to its unique electrical and mechanical properties. Our research investigated Carbonyl-rich graphene oxide (CGO) based memristors using a simple and scalable spray coating method. This method offers advantages over other fabrication methods as low cost, the ability to producelarge-area films, and is compatible with various substrates, including flexible substrates, which can enable the development of flexible and wearable memristor devices. Our memristors exhibited excellent stability and reliability, with repeatable resistance-switchingbehavior over hundreds of cycles at a low operation potential of 1 volt and a high differencecurrent range between a high-resistance state and a low-resistance state. We areinvestigating the mechanism behind resistance switching by analyzing the structural and chemical changes in the CGO film during device operation. The hypothesis is that the migration of the oxygen functional groups in the CGO film causes resistance switching. Ourpreliminary results demonstrate the feasibility of using a simple spray coating method tofabricate CGO memristors for various applications in organic electronics and show significant potential as next-generation electronic devices.

Fabrication and comparison of electrochemical sensors based on polymeric and carbon materials

Marystela Ferreira[1], Cristiane Carla Maciel[2]

[1]Universidade Federal de São Carlos - Campus Sorocaba (*DFQM*) , [2]Universidade Estadual Paulista

e-mail: marystela.ferreira@gmail.com

This work presents the fabrication and characterization of a flexible electrochemical sensor composed of polymer poly(butylene adipate-co-terephthalate) (PBAT) and Carbon Nitrite Dots (CNDs) or graphite. The materials were characterized by Cyclic Voltammetry (CV), FTIR and contact angle. FTIR analysis of the PBAT/CNDs composite allowed verifying that the insertion of the CNDs in the polymeric matrix modified the spectrum when compared to neat PBAT, since the composite spectrum presents characteristic bands of the CNDs, at 3200 cm^{-1}, attributed to the stretching vibrations of the OH groups and another at 3420 cm^{-1} corresponding to the absorption of the aromatic compound and C-H stretching vibration in aromatic rings. Based on the comparison of the spectra, a modification was observed in the spectrum of the composite based on PBAT and CNDs, indicating the presence of CNDs in the polymer matrix [1]. The measured values of the contact angle for PBAT, exhibited values of the 89.5° ± 1.8°, and the PABT/CNDs electrode was 60.1° ± 0.2°. CV and EIS were usedto compare the electrochemical behavior of the sensor produced using PBAT/graphite (g-PBAT), and the PBAT/CNDs electrodes with and without the application of UVB light. g-PBAT electrode showed higher electrochemical activity compared to the electrode with PBAT/CNDs. However, it was taken into account the amount of material used for the development of electrodes was, since PBAT/CNDs used 10% of CNDs in proportion m/m compared with g-PBAT electrodes the amount of graphite used to 200% in proportion m/m, So the PBAT/CNDs electrode allowed the development of a sensor that uses little material, with low cost and accessible materials. These sensors simultaneously detected emerging pollutants such as cadmium and copper, including real tap water samples, in the concentration range of 0.1 to 1.0mM.

e-mail: florian.gunther@unesp.br

The interconversion dynamics between charge-transfer-state charges (CTCs) and separated charges (SCs) is still an unresolved issue in the field of organic photovoltaics and has therefore remained highly debated in the literature [1]. Although, ultrafast techniques, such as transient absorption spectroscopy (TAS), bring invaluable insights [2,3], the attribution of the obtained absorption characteristics to the charged species often require knowledge about the photophysical properties of the system and its components. Such information canbe obtained from time-dependent density functional theory (TD-DFT). In this conference contribution, a case study on α-sexithiophene:fullerene (α6T:C60) systems will be presented,for which TAS measurements revealed two charge species with distinct absorption characteristics and different dynamics. Modelling the different charge transfer configurations that occur in system with different morphological structures, TD-DFT simulations identified the species as CTCs and SCs. It is found that the spectral differences arise from broken symmetry in the charge transfer state that turns forbidden transitions into allowed ones. Based on this assignment, a kinetic model could be formulated allowing the characterization of the charge generation, separation, and recombination mechanisms.

Insertion of Carbon Nanotubes in Langmuir-Blodgett films of phospholipids and galactose oxidase for bioelectronics

Luciano Caseli[1], Gabriel Nerath[2], José Roberto Siqueira Junior[3] [1]Universidade
Federal de São Paulo (*Department of Chemistry*) , [2]Universidade Federal de
São Paulo, [3]Universidade Federal do Triângulo Mineiro

e-mail: lcaseli@unifesp.br

Inserting carbon nanotubes in Langmuir-Blodgett (LB) films of enzymes confined in lipids can improve their catalytic performance, which is interesting for bioelectronics since robust biosensors can be assembled. In this work, we incorporated the enzyme galactose oxidase and carbon nanotubes from the aqueous subphase in fatty acid Langmuir monolayers and transferred them to solid supports as LB films to essay the catalytic activity towards the catalyzes of the oxidation of D-galactose. Surface pressure-area isotherms, surface potential-area isotherms, polarization-modulated infrared reflection-absorption spectroscopy, and Brewster angle microscopy characterized the floating monolayers. The adsorption of the enzyme at the air-water interface expanded the lipid monolayer, altering the film compressibility at high surface pressures. PM-IRRAS spectra showed amide bands, revealing the structuring of the enzyme into helices and sheets. The monolayers were transferred to solid supports as LB films and characterized with fluorescence spectroscopy and quartz crystal microbalance. The catalytic activities of the films were measured and compared to the homogenous medium. Viability as sensors was tested with voltammetry and impedance measurements. The enzyme accommodated in the LB films preserved the catalytic activity, and carbon nanotubes helped conserve the catalytic properties for moreextended periods of storage. The method presented in this work allows for enhanced catalytic activity and can help explain why specific film architectures exhibit improved performance.

Layer-by-layer film containing reduced graphene oxide and manganese dioxide nanocomposite for supercapacitor electrodes

Danilo Alves Oliveira[1], Jodie L. Lutkenhaus[2], José Roberto Siqueira Junior[3]

[1]Universidade Federal do Triângulo Mineiro (*Departamento de química*), [2]Texas A&M University (*Department of Materials Science and Engineering*), [3]Universidade Federal do Triângulo Mineiro

e-mail: daniloalves2902@hotmail.com

Seeking for new materials combinations and approaches are essential to achieve new nanocomposites with enhanced performance. Carbon materials and metal oxides have been used in energy storage as the their ideal combination can lead to devices with improved power and energy densities [1-3]. Here we present the fabrication of a layer-by-layer (LbL) film containing manganese dioxide (MnO2) nanostructures embedded into reduced graphene oxide (rGO) sheets and arranged with poly(allylamine-hydrochloride) (PAH) for supercapacitor application. Scanning electron microscopy images confirm the incorporation of MnO2 nanostructures into the rGO layers, and cyclic voltammetry and galvanostaticcharge-discharge measurements reveal the electrocapacitive features of the films. Nanostructured PAH/rGO-MnO2 LbL films containing 20 bilayers lead to a supercapacitor with high areal capacitance of ca. 112 mF/cm2 at 1 mV/s and 460 F/g at 1 A/g, in addition to a high capacitive retention performance of 99% over 10,000 cycles and a high charge-discharge time of ca. 600 s. These findings show that the presence of manganese dioxide improved the capacitance, which was twice higher than a blank system of PAH/rGO. Such properties demonstrate, therefore, that the PAH/rGO-MnO2 LbL film is a promising architecture to be further explored in energy storage nanostructured systems.

Mapping the electric field within polymeric transistorsby sum-frequency generation microscopy

Marcos da Silva Sousa[1], Paulo Barbeitas Miranda[2]

[1]Instituto de Física de São Carlos- USP, [2]Universidade de São Paulo (*IFSC*)

e-mail: marcos.silva_sousa@ifsc.usp.br

Organic transistors have the potential to enable novel types of devices and applications that were previously impossible with traditional inorganic materials. In order to fully exploit the potential of these devices, it is crucial to investigate the physical and chemical events that occur within them. In this context, understanding the distribution of the electric field across the dielectric and semiconducting layers of an operating organic field-effect transistor (OFET) could provide valuable insights, particularly for comparing with theoretical models of these devices. In our work, we employ sum-frequency generation (SFG) vibrational spectroscopy [1] to probe the C=O stretch in the polymeric dielectric (PMMA). SFG is a non-linear optical effect that is very sensitive to breaking of inversion symmetry, such as the molecular alignment induced by an intense electric field. In addition, this technique offers the advantage of preserving the integrity of the device and avoiding any modification of the probed charge distribution. In this contribution, we will present SFG images obtained from OFET channels that utilize P3HT and PMMA as the organic semiconductor and organic dielectric, respectively. They are effectively mapping the spatial charge distribution within the OFET channel under operation. If time allows, we also will provide preliminary electrical and SFG microscopy measurements obtained from ambipolar OFETS based on PDBT-co-TT. With this study, we hope to contribute for a better understanding of the physics of OFETs, with important implications for improving their performance.

e-mail: omarbello@usp.br

In recent years, organic materials have attracted significant attention due to their potential for applications in a range of optoelectronic devices, such as optical switches, modulators, and frequency converters [1,2]. In addition, a number of molecular design techniques are being used to enhance the linear and nonlinear optical (NLO) properties in such materials, achieved through structural modifications and chemical design [2]. The imidazo[4,5-b]pyridine (Impy) molecules, primarily recognized for their biological and biochemical activities, have emerged as a promising nonlinear material for multiphoton absorption processes (MPA) due to their planar structure, high electronic density, and ease of synthesis [1,2]. Specifically, Multiphoton absorption has practical applications in various fields, such as 3D optical data storage, photodynamic therapy, microfabrication, and others. For this reason, this study is oriented to investigate the linear and NLO properties of six impy derivates and to evaluate how the introduction of electron-accepting and donating groups modifies its photophysical properties. The optical characterization, including the two-photon absorption (2PA) process, was performed using the Z-scan technique and other spectroscopic techniques. As a main result, an increase in most photophysical parameters was observed in molecules with a dipolar structure D-π-A in relation to molecules with A- π -A structures. Similarly, D- π -A molecules showed higher values for the 2PA cross-section, indicating less influence of electron acceptor groups on the 2PA properties.

In recent decades, the field of photonics has seen exponential growth, reaching applications ranging from optical communication to medical devices. This success lies in the continuous exploration of new ways to manipulate light and the study of optical properties of materials that can be integrated to further photonics applications. This progress highlights the importance of the optical characterization of materials with technological potential. In this regard, materials that exhibit third-order nonlinear phenomena attract much attention. Their understanding has given essential steps in advancing new technologies, such as high-resolution microscopy, all-optical switching, and direct laser writing, to name a few. Among third-order effects, Kerr nonlinearities are one of the most studied effects, being described by the intensity-dependent refractive index $n = n_0 + n_2 I$. For this reason, the spectrally-resolved characterization of the nonlinear refractive index n_2 allows new materials to be identified as candidates for different photonic applications. In this work, we present the n_2 spectra of polymers that have been used in direct laser writing technologies [1]. In particular, we used resins obtained by photopolymerization and studied how different monomer compositions affect the n_2 by using the nonlinear ellipse rotation technique from the visible and near-infrared range [2]. We compared the n_2 thus obtained with reported values for fused sílica, the most widespread material used as a nonlinear reference, and we found values significantly higher for the polymers, demonstrating the potential of these materials.

OLEDs for lighting: is simplifying the structure the best way?

José Carlos Germino[1], Manish Kumar[1], Luiz Pereira[1]

[1]Universidade de Aveiro (*i3N/Departamento de Física*)

e-mail: kakagermino23@gmail.com

Lighting technology is changing rapidly towards an enhanced area of research looking for the best solutions to get highly efficient, long-life and architectural appellative products. Solid State Lighting technologies based on Organic Light Emitting Diodes (OLEDs) became the focus of huge scientific research in recent years due to their unique properties. In particular, the white-OLED can be fabricated, using the unique properties of organic semiconductor carrier dynamics, in a simple device with only an active layer. In a similar way, signage, employing large area OLEDs in different color emission, are also in focus. However, several drawbacks, particularly focusing on emission efficiency and uniformity as well as thermal stability, should be overcome.

With the new generation of organic emitters based on the Thermally Activated Delayed Fluorescence (TADF) process, a new framework has been opened. With a theoretical internal efficiency of 100% due to full triplet harvesting, these organic materials appear to be the best candidates for large-area OLEDs. This work focuses on the large area (16cm2) OLEDs based on TADF emitters. The materials used are the 2- [4-(diphenylamino) phenyl] - 10, 10- dioxide-9H - thioxanthen-9- one (TXO-TPA, red emitter), the (2,5 -Bis(4-(10H -phenoxazin-10-yl)phenyl)-1,3,4-oxadiazole) (DHPZ-2BI ,green emitter) and 10,10'-(4,4'-(4-phenyl-4H -1,2,4-triazole-3,5-diyl)bis(4,1-phenylene))bis(10H -phenoxazine) (2PX-TAZ, blue emitter). The results show good efficiencies, up to 18% of external quantum efficiency (EQE), in only three layers device. An explanation about the physical process is provided, considering both charge carrier injection/transport limits and involving the host: guest molecular interaction, as one the fundamental key to the success. Device simplicity versus efficiency, points to the viability of simple structures, opening new frameworks. Further pathways to improve large-area OLEDs efficiency are discussed.

Organic mixed ionic electronic conductor based onwater-soluble melanin/PEDOT:PSS blend to bioelectronics and energy storage applications

Natan Luis Nozella[1], Miguel Henrique Boratto[1,2], João Victor Morais Lima[1], Nayrim Brizuela Guerra[1], George G. Malliaras[2], Rafael Furlan de Oliveira[3], Carlos Frederico de Oliveira Graeff[1]

e-mail: n.nozella@unesp.br

Organic mixed ionic-electronic conductors (OMIECs) have gained attention due to their capability to efficiently transport and couple both ionic and electronic charges, specially to bioelectronics and energy storage devices applications [1]. Poly (3,4-ethylenedioxythiophene): poly (styrenesulfonte) (PEDOT:PSS) is the benchmark OMIEC, which shows a high electronic mobility but a lower volumetric capacitance in comparison with other organic materials [1]. Eumelanin is a biopolymer that possesses a variety of carboxylic acid moieties [2] that are capable to uptake cationic species in aqueous media and favoring the ionic-electronic coupling in the polymer [2]. Different mass ratios of synthetic melanin (Mel) and PEDOT:PSS have been characterized by a variety of techniques, such as atomic force microscopy (AFM), Fourier Transform Infrared (FTIR) and UV-Vis spectroscopies, electrochemical impedance spectroscopy (EIS), among others. Current-voltage and EIS measurements show that the electronic conductivity of the PEDOT:PSS is preserved (87 ± 24 S $cm^{-1}$to 2 ± 1 S cm^{-1}) while the volumetric capacitance of the films reaches values of 1.5 x 103 F cm^{-3}, showing a clear improvement of the ion-electron coupling in such samples. Finally, we exploited the potential of PEDOT:PSS/Mel blends in an organic electrochemical transistor (OECT) and a supercapacitor (SC). The OECTs exhibit state-of-the-art transconductance (10.8 ± 2.9 mS) while SC showed specific capacitance of 8 F g^{-1}, and 0.62 ± 0.01 Wh $kg^{-1}$and 190.3 ± 5.7 W $kg^{-1}$of specific energy and power, respectively. We believe that the blend of melanin with PEDOT:PSS can be a powerful strategy towardsnew development of OMIECs and related applications, for example, in sustainable iontronicsand bioelectronics.

Reservoir computing: Using conjugated polymers for constructing physical reservoirs

Rafael Francisco Santiago De Souza[1], Gregório Couto Faria[2,3], Bruno Bassi Millan Torres[4]

[1]Instituto de Física de São Carlos - USP (*Grupo de polímeros "Prof. Bernhard Gross"*) , [2]Universidade de São Paulo (*Instituto de Física de São Carlos*) , [3] Instituto de Física de São Carlos da Universidade de São Paulo (*FCM*) , [4]Instituto de Física de São Carlos - USP (*Grupo de polímeros \"Prof. Bernhard Gross\"*)

e-mail: rafael.francisco.sousa@usp.br

Reservoir computing is a new concept that emerged in the early 2000s, which employs the nonlinear dynamics of physical systems, or reservoirs, as a neural network. Unlike traditional neural networks, which require pre-training of all elements, a non-classical reservoir operates without training. The reservoir takes advantage of the nonlinear dynamics of its elements to transmit information, and only the outlet layer of the reservoir is trained for the desired regression or classification [1]. In this research, physical reservoirs were created using electropolymerized conducting polymer microfibers based on EDOT. The authors found that EDOT microfibers were easily grown using a sinusoidal voltage with amplitudes between 2 and 10 V and frequencies ranging from 25 to 200 Hz. Physical reservoirs were then built by placing a monomeric solution in contact with several gold electrodes and applying a sinusoidal voltage to enable polymeric fibers to grow and connect to the electrodes. The physical reservoirs made using EDOT were evaluated for their varied dynamical responses, fading memory, and nonlinear transformations. Additionally, a single fiber of PEDOT was grown on patterned golden substrates, enabling the authors to use the fiber as an Organic Electrochemical Transistor (OECT) [2] and extract information about the transfer and output curves. These classical characterization curves can be utilized to measure performance in OECTs, providing information about the non-linear behaviors coming from a single fiber, which is the elementary persona in a physical reservoir built with polymer fibers.

Screened optimally tuned range separated hybridfunctionals for solvated molecular systems

Thiago Branquinho de Queiroz[1], Reinaldo Vieira Dantas Filho[2]

[1]Universidade Federal do ABC (*Centro de Ciências Naturais e Humanas*) , [2]Universidade Federal do ABC (*Centro de Ciências Naturais e Humanas (CCNH)*)

e-mail: thiago.branquinho@ufabc.edu.br

Since the introduction of the optimally tuned range separated hybrid (OT-RSH) functional,[1] density functional theory (DFT) and time-depedent DFT (TD-DFT) have predicted ground and excited state properties with remarkable accuracy. It relies on splitting the Coulomb operator into short and long range terms, with the short range being represented by a local or semilocal approximation and the long range by the exact Fock exchange (imposing the correct asymptotic on the xc-potential, 1/R). The range separating parameter (ω) is chosen such ionization energies are as closest as possible to frontier orbitals eigenvalues (an exact property). However, the representation of chemical environment has some caveats. A non-periodic molecular system can be represented by a multimolecular system and by optimally tuning such large system one can correctly describe its ''''solvated'''' properties. Though quite accurate, this later strategy is computationally expensive. An alternative is to combine the functional optimization with a continuum solvation model. In the standard implementation of these methods the point charges representing electrons and ions are both free to react to the solute''s charge density, thus, only partial ionization energies can be calculated, leading to an exceedingly low ω. Refaely-Abramson et al. have demonstrated that by employing an asymptotic constrain of the OT-RSH functional to 1/ε the Coulomb attenuation is correctly represented in periodic systems.[2] In this presentation, we overview these incompatibilities and present a screened OT-RSH functional that comply with the concept of optimally tuning in a chemical environment. Its performance is attested by contrasting experimental ionization energies and optical gap with calculated ones for molecular systems of interest in organic electronics.

Study and optical characterization of the poly (3-methythiophene) electrochemically synthetized

Ruth Guimarães da Silva Soares[1], Júlio Goulart dos Santos[2], Francisco Nascimento Silva[3], Cássio Araújo Nascimento[2], Romildo Jerônimo Ramos[3], Eralci Moreira Therézio[3]

[1]Universidade Federal de Mato Grosso (*Física*) , [2]Universidade Federal de Mato Grosso, [3]Universidade Federal de Mato Grosso (*Instituto de Física*)

e-mail: ruth.silva@fisica.ufmt.br

The semiconductor polymer Poly (3-methylthiophene) (P3MT) is highly efficient, inexpensive and electrically conductive, which increases the interest in researching it, as it is within the sustainable consumption standards that scientists and companies seek to develop. The objective of this work is to carry out the electrochemical synthesis of P3MT, to study the optical and structural properties via ultraviolet-visible absorption (UV-Vis), photoluminescence (PL) and excitation photoluminescence (PLE) spectroscopy, to analyse the emission, absorption, energy and bandgap bands. As a result, the UV-Vis spectra were obtained, which made it possible to get the average energy gap of the P3MT, presenting the π-π* transition band and a bipolaron band. Thus, it was possible to characterize and quantifythe energy transfer mechanisms of photoexcited carriers. Furthermore, the cyclic voltammetry data made it possible to calculate the P3MT electronic bandgap. The main results found were: (1) the energy gap value for samples synthesised with $Et_4NBF_4$is 2,18 eV-575 nm and for the electrochemically reduced one 2,10 eV-590 nm; (2) the π-π* transition band of the electrochemically reduced sample compared to the oxidised sample shows a slight shift towards lower energie (3) through the normalised PL spectrum, the deconvolution is obtained, considering two contribution channels. Therefore, it can be concluded that the technique used for the electrochemical synthesis of poly(3-methyl thiophene) is generally simple and easy to understand and that films with the more significant formation of P3MT are more electronegative, which increases the possibility of being applied in electronic devices, such as optical sensors, but further studies are needed to be applied in electronic devices, such as photovoltaic cells.

Study of the influence of the dopant in the PAni thin film on the energy transfer of the PAni/P3OT interface

Júlio Goulart dos Santos[1], Romildo Jerônimo Ramos[2], Alexandre Marletta[3], Eralci Moreira Therézio[2]

[1]Universidade Federal de Mato Grosso, [2]Universidade Federal de Mato Grosso (*Instituto de Física*) , [3]Universidade Federal de Uberlândia (*Instituto de Física*)

e-mail: juliog@fisica.ufmt.br

Conjugated polymers have optical and electrical properties of interest for application in organic electronic devices such as OLEDs and OPVs. Polyaniline (PAni) can be synthed as a thin film and has several oxidation states, in which the emeraldine salt state is the most conductive. The regioregular Poly(3-octyl-thiophene) (P3OT) has photoluminescent and electroluminescent properties and a high solubility and can be quickly deposited in the form of a thin film through various techniques. To form the polymeric interface of PAni and P3OT thin films, PAni was first deposited by cyclic voltammetry using a 0.1 M concentration of two different dopants: hydrochloric acid (HCl) and sulfuric acid (H2SO4). PAni has deposited on a fluorine-doped tin oxide (FTO) substrate. The regioregular P3OT was dilutedin chlorobenzene in a 1/0,1 ratio by mass and deposited on the PAni films by spin-coating. Samples of pure PAni and P3OT films were deposited on FTO to compare with the interfaces. UV-Vis absorption measurements were made and the spectra show a maximum absorbance of 520 nm for the P3OT film and 350 nm for the PAni films. The UV-vis spectrum of PAni-HCl does not show the intense polaronic band at 800 nm, which indicates fewer defects. The absorbance spectrum of the PAni/P3OT interface showed an overlap of the PAni and P3OT spectra. Photoluminescence (PL), atomic force microscopy (AFM), emission ellipsometry (EE), and electrochemical impedance spectroscopy (EIS) measurements will be made. Through photophysical, electrochemical, and morphological measurements, it is possible to analyze the influence of the dopant on the deposition of PAni on the PAni/P3OT interface, to evaluate the transfer of energy between the polymeric chains. Finally, the interest of this study is to analyze the polymer/polymer interaction of the PAni/P3OT interface.

Synthesis and Characterization of New Potential TADF Copolymers for the Development of OLED Devices

Daniela Corrêa Santos[1], Guilherme Costa Coutinho[1], Renata da Silva Cardoso[2], Jilian Nei de Freitas[3], Maria de Fátima Vieira Marques[4]

[1]Universidade Federal do Rio de Janeiro (*IMA*) , [2]Instituto de Macromoléculas Profesora Eloisa Mano, [3]Centro de Tecnologia da Informação Renato Archer, [4]Universidade Federal do Rio de Janeiro

e-mail: daniela.correa@ima.ufrj.br

Organic Light Emitting Diodes (OLED) are widely studied for their advantages. One of the main challenges is the formation of emitters with pure color and high efficiency [1]. The investigation of new polymeric emitters is of great interest in the scientific community, as is the case of thermally activated delayed fluorescence (TADF) emitters [2]. This project focuses on synthesizing new TADF copolymers with two different acceptor units, diphenylsulfone, and anthraquinone, to obtain color emitters, blue and red, respectively. A 2-step synthetic route was followed: first, the addition of the acceptor to the 2,5-dibromocarbazole nitrogen by SN2 (M1, M2). Then the reactive bromine side chain was changed to the boronic acid pinacol ester unit (M3, M4). The copolymers were produced by the Suzuki-Miyaura reaction between M3 or M4, (9-(9-heptadecanyl)-9H-carbazole-2,7-boronic acid bis(pinacol)ester) and a spacer (1,4-dibromobenzene or 1,4-dibromo-2,3,5,6-tetrafluorobenzene). The proportion of units varied between 20:30:50 and 10:40:50, respectively. 1H- and 13C-NMR spectra of the monomers exhibited predictable characteristic peaks, and the polymers showed broad peaks as expected. TGA measurements showed high thermal stability (>400 °C). Furthermore, the UV-Vis spectroscopy results showed absorbance in the blue region. The anthraquinone-containing polymers exhibited a redshift compared to the others. The polymer band gap was around 3.0 eV suggesting a blue emission, and slightly lower for the red polymers. Furthermore, the polymers showed the expected color emission under 365 nm irradiation. The emission mechanism of the polymers will be studied, and later, these materials will be applied as an emission layer in new OLEDs.

Synthesis of PEDOT:PSS Conductive Inks: Do Byproducts of the Chemical Route Influence the FinalProperties of the Ink?

Germán Darío Gómez Higuita[1], Gregório Couto Faria[2]

[1]Instituto de Física de São Carlos - USP (*Física e Ciência dos Materiais*) , [2]Instituto de Físicade São Carlos- USP (*Física e Ciência dos Materiais*)

e-mail: g.gomez@usp.br

PEDOT:PSS, a type of conducting polymer widely utilized in organic electronics, has gained significant attention in various applications, including electrodes, supercapacitors, and sensors, owing to its distinctive properties. Despite extensive research on PEDOT:PSS, onlya limited number of publications have examined the relationship between the properties of conductive inks and the parameters of their synthesis, highlighting a topic that remains largely unexplored. Specifically, there is insufficient knowledge about the influence of chemical byproducts on the final properties of PEDOT:PSS. In a previous study, it was demonstrated that the variation of oxidant agent (OA) during the synthesis of PEDOT:PSS has an impact on the charge density of the final polymer films.[1] This effect was attributed to the reduced rigidity of PSS−(aq) chains, brought about by the screening of electrostatic interactions of sulfonate groups (SO3−) with OA ions. Consequently, the ability to couple charged PEDOT+ with the PSS− counterpart is diminished. However, it remains unclear whether the counterion of PSS− also affects the collective dynamics of charged chains in solution and its implications for the electrical properties of PEDOT:PSS.

This study presents the results of Dynamic Light Scattering (DLS) measurements of PSS solutions with different counterions, including the poly-acid (PSS−-H+) and the poly-salt (PSS−-Na+) forms. Additionally, the electrical characterization of PEDOT:PSS/PSSNa filmswas conducted using the four-point probe method. The DLS measurements revealed that PSSNa chains exhibit lower electrostatic rigidity compared to PSSH chains. Furthermore, itwas observed that the same addition of OA to the solution causes greater contraction in chains of the poly-salt than those of the poly-acid, further impeding the coupling of PEDOT+and PSS−. This observation aligns with the findings from the four-point probe, which indicate that PEDOT:PSS ink synthetized with PSSNa show conductivity values that are 10times lower than those using PSSH.

Due to their large exocyclic bond angle 5-membered heterocyclic rings are at the edge between rod-like and bent-shaped liquid crystals (LCs). Polar properties that emerge in the macroscopic structure in this type of materials of the LCs are dependent on this geometrical parameter. Such structural features tends to show a distinct nematic (N) phase, being called bent-core nematics (BCNs), characterized for a local biaxiality by smectic clusters (cybotactics) formation into the nematic phase (Ncyb) or twist-bend nematic (NTB) mesophase.[1][2] In this work we have synthesized a new set of 3,5-diarylisoxazoline/isoxazole esters in which the overall shape of the structures are at the boundaries of rod-shaped and bent-shaped LCs. The liquid crystals behavior was investigated and the data were compared with the diarysubstituted oxazadiazoles.[3] The liquid-crystalline behavior was characterized by POM, DSC and XRD studies. All molecules exhibit LC phases, except one derived from isoxazoline ring. Nematic mesophase as detected with a helicoidal growing during the transition to the SmC phase for most of the esters investigated in this study.

Although extensive research has been conducted on polymeric nanocomposites for sensor applications, the use of PANI-based nanocomposites in impedimetric and capacitive electrochemical sensors remains largely unexplored. The objective of this study is to investigate the relationship between the composition of nanocomposites and the sensitivity and linearity of electrochemical impedimetric and capacitive pH sensors. PANI/CeO2 and PANI/WO3 thin films were produced through spin coating, characterized and subsequently used in electrochemical impedance spectroscopy (EIS) and capacitance spectroscopy (ECS) platforms. The results showed an optimized performance for the devices depending on the composition of the sensing thin film. Specifically, PANI/CeO2 composite exhibited a 213% increased ECS sensitivity when compared with pristine CeO2 and an increase of 64% in ECS linearity of PANI/WO3 in relation to the polymeric sensitivity. Despite not as optimized as ECS, the EIS method also resulted in an incremented sensitivity for the composites: 20% for PANI/CeO2 and 37% for PANI/WO3 when compared with the sensitivity of the metal oxides. Furthermore, this study investigated the structure-property relation of the considered materials using standard techniques such as scanning electron microscopy (SEM), contact profilometry and absorption UV-Vis spectroscopy. The findings of this work offer promising prospects for future studies on the application of PANI-based materials as chemical sensors.

Surface-Supported Metal-Organic Frameworks (SURMOFs) are crystalline materials based on metallic clusters and organic linkers layer-by-layer grown on functionalized surfaces.[1] These hybrid structures have the intrinsic high porosity and mechanical flexibility of Metal-Organic Frameworks (MOFs).[1] This unique set of co-related properties opens exciting alternatives to create novel hybrid electronics. However, the typical high porosity can result in glassy interfaces and layer disorder during device integration whether conventional evaporation methods are employed. Therefore, one of the ongoing challenges for these structures relies on the elaboration of appropriate methods of integration. In this direction, nanomembrane-origami technology can be a promising tool. This technology can be designed to create rolled-up nanomembranes, providing self-adjustable top contacts on ultra-thin films without physical damage.[2] In this work, we demonstrate the integration of ultrathin HKUST-1 SURMOF heterojunctions using rolled-up nanomembranes as the top electrode. This concept allowed us to access unprecedented physical effects, namely, ambipolar resistive switching and negative differential resistance.[2,3] Employing the same approach, we integrated these structures into a 3D ultracompact capacitor structure to determine their intrinsic dielectric properties.[4] In addition, the experimental results obtained are interpreted with insights from density functional theory (DFT) calculations, ab initio molecular dynamics simulations, and finite-element calculations. These findings show promising perspectives for SURMOF thin-film structures toward novel hybrid electronics.

In recent years, Organic Electrochemical based devices (OEDs) have been the key focus of many developments, mainly in the fields of neuromorphic and bioelectronics [1]. Despite the successful implementation of OEDs, the fundamental processes that regulate their operations and sensing capabilities, specifically those related to ion-to-electron transduction, remain unclear [2]. Consequently, there is a lack of robust models to explain the steady-state and transient characteristics of OEDs and electrochemical biosensors [3]. In this study, we bring new highlights to a thermodynamic-based model that quantitatively describes OEDs'' operation, with a special focus on the Organic Electrochemical Transistor (OECT). Here, we present alternative interpretations to drain current traditional models, based on thermodynamic principles. Beyond that, we conducted a systematic study on the influence of the electrolyte composition on P3HT-based OECT, and analyzed the results in light of the proposed thermodynamic model. By analyzing a large amount of experimental data with distinct electrolytes, we generated guidelines for material design and device development, targeting highly sensitive electrochemical biosensors and devices.

The advent of the pandemic has led to growing interest in self-disinfecting materials, mainly because other variants and similar viruses may appear in the future[1]. In the present study, for the first time, it was demonstrated that natural and synthetic fabrics could gain virucidal properties after the impregnation of a stable free radical. Cotton and polypropylene fabrics were modified with the photochemically generated 10H-phenothiazine (PHT) radical cation adsorbed to promote virus elimination. The impregnation of PHT radical cation was evidenced by the UV-visible spectrum showing the fingerprint band at 530 nm[2], FT-Raman spectral changes, and the appearance of radical cation EPR signal. The EPR signal of PHT-treated cotton fabric persisted and intensified after the fabric washing and re-irradiation. Colorimetric test evidenced the persistence of radical cation in PHT-treated cotton fabric even after 2 months in the dark. Viral inactivation assays were performed with the cotton fabric and the polypropylene face mask treated with PHT. Results of qPCR showed that cotton fabric impregnated with PHT radical cation presented a two hundred twenty-four-fold reduction in the viral genome compared to the original cotton fabric. Face masks treated with PHT reduces genome copies by ten times. Oxidative attack of PHT radical cation on virus envelope was evidenced by the quenching of EPR signal of fabrics exposed to a model of virus envelope and by cryo-TEM (cryo-Transmission Electron Microscopy) images showing virus destruction. One advantage of the pro-oxidant attack is the non-specificity that allows efficiency against different viruses and bacteria.

A drift-diffusion model based on fundamental material parameters for organic electrochemical transistor devices: steady-state and transient description

Andres David Peña Unigarro[1,2], Florian Steffen Günther[3,1] [1]Universidade de São Paulo (*Instituto de Física de São Carlos*) , [2]Technische Universität Chemnitz (*Institut für Physik*) , [3]Universidade Estadual Paulista (*Departamento de Física, Instituto de Geociências e Ciências Exatas, Câmpus de Rio Claro*)

e-mail: a.unigarro@physik.tu-chemnitz.de

Among all the different devices of organic electronics, organic electrochemical transistors (OECTs) are particularly interesting as they have emerged as potential transducers in applications that require the conversion of ion fluxes to electronic current [1], For the rational optimization and understanding of the fundamentals of OECTs and OECT-based applications, however, it is essential to have theoretical models capable to predict and recreate the experimental data. In our work, we formulate a model that describes the ion flux from electrolyte into the semiconducting layer based on drift and diffusion by making use of intrinsic material parameters. While our model exhibits an analytical solution for steady-state conditions, the differential equation to describe the transient behavior requiresa numerical treatment. In doing so, our approach goes beyond other drift-diffusion models[2], which exhibit limitations as they making use of boundary conditions that enable analytical solutions. In particular, our approach allows simulating the doping level along the source-drain channel, a non-uniform electric field and non-constant diffusion coefficients as consequence of the material differences between electrolyte and semiconductor. In this contribution, we present simulated steady-state properties such as the drain current as a function of the gate voltage and compare our results to other models from literature. We found qualitative good agreement to trends of the recently published thermodynamic model [3], although the modeling approach is fundamentally different. Furthermore, the impact of the model parameters on the transient responses will be presented and analyzed.

Al/MEH-PPV/ITO organic memory device: characterization and ambient effect

Claudio de Oliveira A. Castro[1], Yasmim Mayra Sales dos Santos[1], Ángel Alberto Hidalgo[1], Helder Nunes da Cunha[1], Alexandre de Castro Maciel[1], Maria Leticia Vega[1]

[1]Federal University of Piauí (*Physics*)

e-mail: xclaudio651@gmail.com

Devices were prepared using an ITO bottom electrode (BE), MEH-PPV film as the semiconductor layer, and a 100 nm thick aluminum layer was thermally evaporated as the top electrode (TE). Electrical measurements, current vs. voltage (I-V), and spectral impedance were performed with the device under vacuum and ambient conditions. The electroforming process occurred under a vacuum and was monitored using both techniques. I x V measurements show diode-like behavior when the device is pristine. At the end of this electroforming, two conductive states are observed: the HRS (High Resistance State) and LRS (Low Resistance State). The observation of these two conductive states was considered memory behavior. In this situation, the device switch between both states using precise voltages on direct and reverse polarizations, classifying the device as bipolar [1]. In contrast to the pristine state, the LRS and HRS states are characterized by ohmic transport. Impedance measurements were also intercalated into I-V sweeps to study the frequency response of the device. Before memory behavior is observed, the device exhibits effects that are not purely capacitive. Once memory behavior is observed, LRS and HRS states have well-defined responses fitted by an equivalent circuit model, which is an association of a resistor in series with a resistor and a constant phase element (CPE). A CPE element is characteristic of different transport processes with different time scales, consistent with the development of conducting filaments [1]. After characterization under vacuum, samples were exposed to ambient conditions and characterized again. The impedance of the LRS and HRS states approach each other and relax slowly to the pristine state in approximately 2 h. To see LRS and HRS states again a new electroforming process under vacuum is necessary.

Alternative biocarbon counter-electrode for optical electronic device

Karolayne Emanuelly Gomes Xavier[1,2], Cícero Inácio da Silva Filho[2], Taisa Cristine de Moura Dantas[2], Giovanna Machado[2]

[1]Universidade Federal de Pernambuco, [2]Centro de tecnologias estratégicas do Nordeste

e-mail: karolayne.xavier@ufpe.br

Facing the environmental challenges of energy crisis and global warming, the use of carbon materials has emerged in the development of renewable energy due to their excellent conduct properties, high physicochemical stability and promising application as counter-electrodes substituting expensive noble metals, such as Au or Ag. In addition, materials obtained from biomass sources have increased due to their wide availability, low-cost processability, adjustable band gap that ensure efficient charge transfer between the interfaces of a photovoltaic device, compared to other materials based on biomass [1,2]. Biocarbon counter-electrode enable the use of recyclable waste of organic matter to reduce the environmental impact. In this work, biocarbon were produced through the carbonization of biomass from sources of sugarcane bagasse and were introduced into the carbon paste to replace the traditional carbon black derived from oil residues. The carbon paste is prepared by ball-milling a mixture of carbon black, graphite powder and $ZrO2$ powder [3]. Carbon black plays a crucial role on the photovoltaic work function, which affects the charge extraction and eventually influences the overall device efficiency. With the resulting carbon paste, films were devised and analyzed for crystallinity and biocarbon morphology, characterized by X-ray diffraction and scanning electron microscopy. Were investigate the work function, sheet resistance and Interfacial connection as well. The use of metallic electrodes is a major obstacle to be faced for the upscaling of solar cells, through that perspective the biocarbon material is a promising substitute for the expensive Au and Ag CE for low cost solar cells.

Pure fluorescent emitters employ only singlet excited states for eletroluminescence, limiting its efficiency up to 25%, determined by spin statistics. Thermally Activated Delayed Fluorescence (TADF) mechanism allows the harvest of non-emissive triplet states into emissive singlet states via intersystem crossing process. Reached when decreasing the ∆stat KbT energy level that requires a spatial separation of the High Occupied Molecular Orbital (HOMO) and the Low Unoccupied Molecular Orbital (LUMO) in the molecule. Charge transfer state, in Donor-Acceptor molecules, is a way to promote this spatial separation. Here, we present the optical spectroscopy investigation and concept proof, of a pure organic small molecule, based on a phenoxazine (donor) and dibenzothiophene-S,S-dioxide (acceptor). Photoluminescence may vary from an efficient TADF in function of polarity environment.[1,2] The experimental works comprises the time resolved measurements, performed in solution, as well as in solid state, inert matrix, in fucntion of temperature, e.g. time resolved spectra. The basics photophysics were also investigated, in order to fully explore its potential.

Bioimpedance-based Biosensors

Pedro Bertemes Filho[1]

[1]Fundação Universidade do Estado de Santa Catarina (*Departamento de Engenharia Elétrica*)

e-mail: pedro.bertemes@udesc.br

The latest innovations in biosensors and emerging applications have been used to deliver easy-to-use diagnostic systems for healthcare. Today's leading biotechnology companies are developing novel semi-synthetic ligands, aptamers, peptides, and conducting polymers to produce functional systems that can deliver precise molecular information for early diagnosis of diseases. Biosensors are powerful tools for environmental, human and animal health monitoring, especially when they are used with bioimpedance spectroscopy for in situ measurements to determine contaminants in fluidic samples. The objective is to present the Bioimpedance Analysis (BIA) using biosensors as miniaturized and disposable detection devices for specific chemical (or set of chemicals), biomolecules [1], adulterants and microorganism analysis in different fields concerning health point-of-care, food quality [2], food safety and pollution. For that, this work aims to gather original articles and reviews showing research advances, fabrication, innovative applications, new challenges and future perspectives of BIA-based (Bio)sensors in important areas as biomedical engineering, health [3], IoT, agri-food and environmental. BIA has been successfully used for cancer diagnosis and biomaterial characterizations due to its safety, low cost, effectiveness, portability and applicability. The results have been showed that miniaturization of such a device depends on the application, portability, electrode geometry, number of electrodes and working frequency bandwidth. It can be concluded that a biosensor can be applicable to detect the biochemical and biological samples if we fulfill the requirements of simplicity, robustness and sensitivity.

Characterization of thin films of a columnar liquid crystal based on perylene diimide deposited by spincoating and blade coating techniques

Julia Paiva[1], Juliana Eccher[1], Harald Bock[2]

[1]Universidade Federal de Santa Catarina (*Departamento de Física*) , [2]Centre de Recherche Paul-Pascal

e-mail: juliapaiva.ufsc@gmail.com

Liquid crystals (LC) are materials which present intermediate phases between the crystalline solid and the isotropic liquid and are promising organic semiconductors for presenting self-organization and the possibility of molecular alignment on electrodes, providing greater mobility of charge carriers[1]. In this work, we present the characterization of a brand-new thermotropic discotic LC (designated BPD-11) derived from benzoperylene diimide with a hexagonal columnar mesophase at room temperature and investigate its properties in thin films produced by spin coating and blade coating techniques. The mesomorphic characterization of the material was performed by polarizing optical microscopy (POM), differential scanning calorimetry (DSC), thermal gravimetric analysis (TGA) and x-ray diffraction (XRD). The thin films were prepared from a solution using chloroform as solvent. The morphological, structural and optical properties of the films were performed and the results indicated that these films are very attractive for optoelectronic devices applications such as in OLEDs and solar cells.

Charge and energy transport in low-mobility materials represent a challenge for organic photovoltaic devices (OPVs), which makes understanding the potential for interaction between the donor and acceptor species indispensable. In this work, we carried out a study of the intermolecular interaction potential between the complex formed by a regioregular poly(3-hexylthiophene) oligomer (oligo-P3HT) and the functionalized fullerene, [6,6]-phenyl-C_{61}-methyl butyric acid ($PC_{61}BM$). Initially, conformational space was calculated by a systematic grid scan. Then, the lowest energy conformers had their geometry optimized through the Density Functional Theory (DFT) with BLYP functional. Finally, we calculated the interaction potential using the Forcite module available in the Biovia Materials Studio™package (Dassault Systèmes). For this purpose, a code was programmed to rotate both molecules (oligo-P3HT and $PC_{61}BM$) every 5° and 40°, respectively, in the coordinatesx, y, and z. Furthermore, the centroid position of the P3HT oligomer was shifted up to a cutoff distance of 30 Å about the $PC_{61}BM$ for each cartesian axis. For that, oligo-P3HT and $PC_{61}BM$ centroids were initially fixed to equal spatial coordinates. The interaction energy between P3HT:$PC_{61}BM$ complex was calculated for all configurations by applying the Universal force field. Finally, we obtained the configurations with more potent interaction energies, which demonstrate the interaction capacity between of oligo-P3HT and $PC_{61}BM$.

The latest advances with organic semiconductors have provided competitive optoelectronic devices with new functionalities, as observed for OLEDs, OFETs, OPVs and sensors. Liquid-crystalline materials can increase the efficiency of these devices due to their molecular organization that improves charge transport, energy conversion and light outcoupling. In a previous work, we demonstrated that the molecular alignment of a columnar liquid crystal (ColLC) in a diode structure improved the charge carrier mobility in five orders of magnitude and allowed electroluminescence emission [1]. Here, we investigate a triazine-based ColLC (5A) as aligning host for emissive molecules to be applied in the active layer of OLEDs, based on a work where we demonstrated the potential of the photophysical properties of liquid-crystalline triazine-based molecules for alignment-induced enhancement of light outcoupling [2]. As guest emissive molecule we investigated a thermally activated delayed fluorescent compound (CNQxP-TPA), which absorption band overlaps with the emission peak of the triazine-based host in order to optimize energy transfer [3].

Combination of titanium dioxide and quinoline derivative thin films as p-n heterojunction inorganic-organic device

Natalia Carli de Oliveira[1], Lucas Prado Fonseca[2], Lucas Michelão Martins[1], Luis Vicente de Andrade Scalvi[2]

[1]Universidade Estadual Paulista (*Química*) , [2]Universidade Estadual Paulista (*Física*)

e-mail: natalia.carli@unesp.br

Combinations of inorganic and organic materials have become very attractive for applications in optoelectronics. In this communication, the goal is the assembly of thin film heterojunction of titanium dioxide (n-type semiconductor), with quinoline derivatives, which are organic acceptors (p-type) with blue luminescence [1], with great potential to generate a transparent p-n junction, which can act as gas sensor or photoexcitable optoelectronic device. Tin dioxide was obtained by sol-gel-dip-coating with anatase structure when treated up to 600oC and rutile up to 1000oC. The quinolinic derivative (4-(6-(diethylamino)-4-phenylquinolin-2-yl) benzoic acid was synthed according to the literature [2], in which a reaction occurred between the aniline N,N -Diethyl-p-phenylenediamine and the aldehyde 4-Formylbenzoic acid, forming a Schiff's base, which reacted with phenylacetylene for 4 days under agitation in acid medium, giving rise to quinoline. For the pure form, reactive extraction and recrystallization were performed, followed by solubilization in organic solvents. Homogeneous films have been a challenge due to the tendency to form islands and poor adhesion to the substrate. Drop-casting and electrodeposition processes performed better than dip-coating. Different types of solvents, substrates and annealing are being tested. Confocal microscopy revealed that quinolines solved in acetone deposited via drop-casting have good adhesion and homogeneity, with a thickness of up to 1 micron. UV-Vis transmittance for films of quinoline derivatives 2,4-diphenylquinolin-6-amine and 2-(4-methylthio)phenyl)-4-phenylquinolin-6-amine deposited via drop-casting on FTO substrates reveals absorption bands in the range 360-420nm, in agreement with the literature [1].

Controlling the oxidation state of terbium ions of a borogermanate Tb glass by thermo-electrical imprinting treatment

Juliane Resges Orives[1], Lia Mara Silva Marcondes[1], Thierry Cardinal[2], Marc Dussauze[3], Marcelo Nalin[1]

e-mail: juliane_resges@hotmail.com

Borogermanate glasses containing Tb^{3+}ions are interesting materials due to their luminescent and magnetic properties [1]. The most stable oxidation state of terbium ions is trivalent, but terbium also can present the tetravalent state. Glasses containing these two states can present differences in their structural, luminescent, optical, and magnetic properties, this opens up important opportunities in finding a way to modulate the oxidation state of terbium at the microscale. In this work we used the thermo-electrical poling for the transfer of periodical micro-structured motifs on the surface of a glass with the following composition $96(46GeO_2-29B_2O_3-16Na_2O-5BaO-4Al2O_3)-4Tb_4O_7$. The treatment was performed for 30 min, at 300 °C and a DC bias of 1 kV using an electrode with squared motifs of 40 x 40 μm^2distanced by 10 μm width electrically conductive Pt grid [2]. The presence of molecular oxygen due to the structural rearrangement shows that the poling was effectivein the contact zones. The sample showed a change in color to yellow only in the poled arealocated under the electrode indicating that oxidation of Tb^{3+}ions to Tb^{4+}had occurred. A broad absorption in the visible region between 300 and 650 nm was assigned to the ionsTb^{4+} in the poled layer. The Luminescence measurements showed that a very nice patternwas created in which in the poled zones the luminescence decreases around 10x, while inthe unpoled zones the luminescence was not modified, confirming the control of oxidation of terbium ions at microscale.

Conjugated polymers have been widely studied due to their potential use in the electronics field. One of the key challenges with organic materials is their propensity to undergo photolytic and photochemical reactions upon exposure to light, which can limit their use in certain applications.[1] In many applications, such as in active layers of organic solar cells, photo, and thermal stability are critical factors for material performance. In this context, the goal of this study was to investigate the degradation of the copolymer poly(9,9-dioctylfluorene)-co-trans-stilbene, also known as PFSTB, which exhibits luminescent and semiconducting properties attributed to the conjugated bonds present in its fluorene and stilbene structure. The characterizations involve absorption, emission and structure properties using UV-Vis, fluorescence and infrared spectroscopy, respectively. This material was deposited by blade coater as a thin film, varying thicknesses (one to five layers) on a quartz substrate and subjected to different periods of light exposure (1h to 24 hours). The luminescent properties of the material were measured before and after exposure to light radiation. The UV-Vis technique revealed an increase in the absorption intensity at 380 nm with subsequent layer additions. After exposure to 254 nm light for 24h, the UV-Vis results show no absorption, indicating the degradation of the conjugated polymer. The results obtained contributed to a better understanding of the photodegradation susceptibility of PFSTB.

Deposition techniques of quinoline-derived organic thin films for coupling with tin dioxide aiming optoelectronic devices applications.

Lucas Prado Fonseca[1,2], Natalia Carli de Oliveira[1], Lucas Michelão Martins[1,2], Luis Vicente de Andrade Scalvi[1,2]

[1]Universidade Estadual Paulista, [2]Pós-graduação em Ciência e Tecnologia de Materiais

e-mail: lucas.prado@unesp.br

With the growing interest in organic electronics, quinoline derivatives (QDs) have been investigated for innovation and improvement of optoelectronic devices, being suitable for light-emitting diodes and optical fibers among others [1]. The purpose of this work is to use QDs in the form of thin film, with the premise of their good mechanical stability, resistance to oxidation and p-type electrical transport characteristics [2], and coupling with tin dioxide (SnO2), a naturally n-type semiconductor due to localized donors sites in the matrix. It forms a hybrid organic-inorganic p-n structure, taking advantage mainly of the HOMO-LUMO quinoline electronic transition through its characteristic Donor-π-Acceptor [3] which may be linked to SnO2 characteristics, leading to a luminescent p-n junction. Obtaining a homogeneous film of QDs for application in optoelectronics has proved to be a challenge. Different types of organic solvents have been used to deposit as thin films, by both drop-casting and spin-coating. Best deposition characteristics reveal films ranging from 0.5 μA to 1.0 μA thick and an optical absorption band at approximately 350 nm, which indicates well-deposited film. The influence of different light sources on the electrical response of the QD layer has been investigated, and a He-Cd laser (325nm) irradiated on the device alters its resistivity by up to 3 times. The high transparency in the visible range of the electromagnetic spectrum of tin dioxide as well as of QDs, along with their electrical responses, make the heterojunction promising for the manufacture of organic-inorganic devices.

Designing low-bandgap S,N-Heteroacene oligomers

Reinaldo Vieira Dantas Filho[1], Thiago Branquinho de Queiroz[1]

[1]Universidade Federal do ABC (*Centro de Ciências Naturais e Humanas*)

e-mail: reinaldo.dantas@ufabc.edu.br

Low-bandgap organic molecules are key actors in organic photovoltaic devices. S,N-heteroacenes (SN) are a promising class of such molecules due to their enhanced conjugation compared to S-acenes and acenes [1]. Dicyanovinyl (DCV) is a chemical functional group with high electron affinity that has been shown to decrease the ionization energies and optical bandgap when coupled with S,N-heteropentacenes (SN5' s) and S,N-heterohexacenes (SN6' s) [2]. In this context, we have investigated a series of SN oligomers containing the DCV group in order to understand how one can control optical and transport gap in such systems. These properties were calculated by time-dependent density functional theory (TD-DFT) calculations using the optimally tuned range-separated hybrid functionals (OT-RSH). In the OT-RSH functional the Coulomb operator is split in short and long-range terms, the first one being represented by semi-local approximations and the second one by exact Fock exchange. The range-separating parameter is selected by enforcing that ionization energies equals to frontier orbital eigenvalues (an exact property in the context of Koopman' s theorem). This functional accurately describes charge transfer, making it suitable for studying conjugated systems. It is observed that the DCV-SN oligomers show smaller ionization energies and optical gaps in comparison to their non-functionalized analogous. It depends, however, in the conjugation number of the oligomer. Thus, in our study we show how to design S,N-heteroacenes with the desired optical and transport gap.

Development and fabrication of multilayered core structure silica doped fiber for second harmonic generation

Salah M. Aljamimi[1], Virgílio de Carvalho dos Anjos[2], Jérôme Lapointe[1], Jacques Albert[3], Younes Messaddeq[4,1]

[1]Centre d' optique, Photonique et Laser - Université Laval, [2]Universidade Federal de Juiz de Fora (*Física*) , [3]Carleton University, [4]Université Laval

e-mail: smabdullah.jamimi@gmail.com

This work deals with the process of design and fabrication of novel multilayered core structured doped silica fiber through modified chemical vapor deposition (MCVD) for second harmonic generation (SHG). This alternative layered structure has been developed with several fabrication cycles which include a different number of layers (4, 8, and 16) with a dopant such as Germania (GeO_2) into a single mode fiber. These multilayered core structure preforms were characterized in terms of refractive index profiles (RIPs), and weight percent using Wavelength Dispersive Spectroscopy (WDX) and Maker fringe measurements to check their potential for non-linear conversion. Then, drawn into fibers while maintaining their primary geometry. The fibers are characterized in terms of propagation properties and second-order nonlinear (SON) conversion through the coupling of pulsed laser beams into the poled fibers samples. Of these, 16-layered fibers have been demonstrated to produce the most intense SHG resulting in two cycles of fabrication to improve green light emission as detected by a regular camera and a Photomultiplier (1000 mV and 1400 mV) even though it was solely exposed to an external thermal poling.

Development of MEH-PPV Langmuir-Blodgett films for anisotropic devices

Maria Leticia Vega[1], Endel Ezequiel Carvalho Costa[1], Marleane M. F. Azevedo[1], Alexandre Castro Maciel[1], Ángel Alberto Hidalgo[1]

[1]Universidade Federal do Piauí (*Física*)

e-mail: marialeticia.vega@ufpi.edu.br

Π-conjugated polymers are widely used as active layers in different optoelectronic devices. However, chain orientation and packing affect charge injection and transport, modifying device performance. The best way to approach this problem is to prepare well-organized films in which the main polymer chains are controlled. In this context, the Langmuir-Blodgett technique becomes an advantageous option, it is possible to obtain an optimization of the organic/inorganic interface, improving charge injection, reducing traps and improving charge transport, generally enhancing devices performance [1,2]. Furthermore, alignment of transition dipole moments will result in polarized absorption and change in emission properties. In this work, we produce Polymeric Light Emitting Diodes (PLED's) using Langmuir-Blodgett films of MEH-PPV to study the correlation between the ordering of the films and device performance. When anisotropic films are used as active layer, we observe that only a fraction of the light (polarized parallel to the polymer transition dipole moment) will be absorbed and the transmitted light portion can be used for other purposes such as absorption by a second active layer. Uv-vis absorption show linear behavior with the number of layers. LB technique introduces partial ordering inducing anisotropic absorption. The dichroic ratio (d) and Huang-Rhys (S) parameter does not show change in solution. In thin films d grows slowly from 1.0 for one layer to 1.3 for 8 layers. On the other hand, S show strong dependence on polarization, indicating that film organization at the interface affects the vibrionic state. Diode devices show polarized light emission.

Developing an efficient energy storage system is crucial for storing energy sources, especially renewable ones that are exponentially increased in the last decade. Supercapacitors have shown significant attraction among the different energy storage systems due to their high-power density, long life cycle, and fast charge and discharge process. Conjugated polymers may be the answer to solve this problem due to their properties, as presented by Polyaniline (PANI). The pseudocapacitive behavior of PANI allows its application in supercapacitor devices with higher power density capacity. In this work, the properties of PANI were combined with Lignin, a biopolymer found in plants and as residue from the pulp and paper industry. Lignin's chemical structure is based on phenylpropane units, which can be oxidized to form interesting products like quinones. These molecules are electrochemically active and can provide two electrons and two H^+ionsper unit, resulting from hydroquinone oxidation into benzoquinone. Herein, PANI-Lignin blends were prepared with variable proportions and tested as electrodes in supercapacitors.The results revealed a capacitance of 518 F g^{-1}at 1 A $g^{-1}$and a retention capacity of 71% after1000 cycles, promising results for developing energy storage devices. The strong interactions between the two materials, provide by hydrogen bonds and π stacking, lead tothe stabilization of the structure of PANI. These bonds act as a bridge to control the volumechange during the charge/discharge process that naturally happens and causes PANI degradation, promoting improved mechanical and electrochemical properties. Therefore, this study shows a low-cost and eco-friendly solution combining industrial recycling wasteand further application in energy storage, creating a potential circular economy through green chemistry.

e-mail: leandro.zucolottococca@gmail.com

Organic π-conjugated molecules have emerged as promising candidates for applications in nonlinear optics, such as optical limiting, optical switching, fluorescent probes, among others, due to the ease of structural modification, which allows for exploring more efficient molecular designs at a relatively low production cost [1]. Among the various organic materials studied, diketopyrrolopyrrole (DPP) derivatives stand out for their high structural planarity and good emissive properties, making them excellent candidates for nonlinear optics research [2]. Here is reported the study of excited state absorption (ESA) in two diketopyrrolopyrrole derivatives containing thienyl moiety and different peripheral groups (hydrogen and bromine) employing the Z-scan and pump-and-probe techniques. It is expected that the structure containing the bromine atom will exhibit an increase in the nonlinear response owing to the higher induced polarizability by the bromine. The results obtained by the Z-scan technique revealed an ESA band around 415 nm, with an excited state cross-section (σ_1n) about 15 times larger than the ground state. In addition, the sample containing the bromine atom showed an approximately 2-fold increase in σ_1n. On the other hand, by the pump-and-probe technique, another ESA band at around 750 nm was observed. These results provide a conceptual proof that diketopyrrolopyrrole derivatives are promising materials for applications in photonic devices.

Dynamics of the Generation and Propagation of Independent OAM Modes in a Photonic Chip

Laura Maísa Souza dos Santos[1], Jonathas Matias de Oliveira[2], J. C. A. Rocha[3], José Vinícius S. Moura[3], Alcenísio Jesus-Silva[3], Eduardo Jorge da Silva Fonseca[3]

[1]Universidade Federal de Alagoas (*Instituto de Física*) , [2]Instituto Federal de Educação,Ciência e Tecnologia de Alagoas (*Campus Coruripe*) , [3]Universidade Federal de Alagoas(*Instituto de Física*)

e-mail: laura.maisa@fis.ufal.br

The remarkable features of the intensity distribution and phase of the orbital angular momentum (OAM) beams have been used for modulating classic and quantum information. Although there is a broad and rich ground of works investigating the free propagation of the structured beams it is still a challenge to incorporate their many degrees of freedom within compact and integrated photonic devices. Recently, Y. Chen et al. [1,2] took an important step forward in this direction, but limited to the OAM modes that can be guided in each structure. Starting at this point, we demonstrated that it would be possible to guide different OAM modes in the same photonic structure. By means of a simple coupling system we could tune the output OAM mode by properly tilting the input beam [3]. The proposal presented here consists of the microfabrication of annular waveguides inside a glassy blade via direct laser writing technique. We understood that the adequate phase matching phase, between the input beam and the Δ parameter, selects the OAM beam modes that will be found in the output waveguide. The results confirmed that a tilted input coupling can selecte propagate different OAM modes and its superpositions inside the photonic chip with high purity. Owing to the degree of freedom of OAM light, OAM circuit photonics can be explored to enhance high- capacity data processing for quantum or classical networking.

e-mail: cristiane.costa@iqb.ufal.br

The aging of fingerprints is a major challenge for forensic science because of the progressive degradation of organic compounds under the influence of several factors: type of suspect latent print residue, texture and condition of surfaces (clean, dirty, sticky, greasy etc.), environmental conditions during and after latent print deposition, and time elapsed since the evidence was touched [1,2]. This work evaluates the effect of the aging of the residues present in the fingerprint on the quality of the images revealed through the electrochemical deposition of poly(3,4-ethylenedioxythiophene) (PEDOT) on stainless steel and cartridge cases. PEDOT was deposited electrochemically by chronoamperometry applying an electrical potential of 0.9 V *vs.*Ag/AgCl for 180 s on stainless steel and cartridge case surfaces. The images of the fingerprints revealed from the electrodeposition of the PEDOT were registered after 1, 7 and 30 days resulting from the application of the fingerprint on the metallic surface. Fingerprint developments show the aging effect of latent fingerprints developed through PEDOT electrodeposition on stainless steel plates and cartridge cases. The contrast between the fingerprint and the metallic surface is noticeable in fingerprints aged for up to 30 days. Papilloscopic details such as line ends, bifurcations and pores were found. This result shows that the amount of sebaceous material present in the fingerprint directly influences the deposition of the PEDOT, since the fat is acting as an inhibiting barrier and indicate that processes involving the electrodeposition of PEDOT on metallic surfaces consist of an efficient methodology to reveal latent fingerprints, even after 30 days in which the sebaceous/eccrine residues were left on the surface.

Effect of TeO2 on optical and 1.06 µm emission in Nd3+-doped phosphate glass for high-power lasers

Radha Mada[1], Seshadri Meruva[1], Maria Jose Valenzuela Bell[1], Virgílio de Carvalho dos Anjos[1]

[1]Universidade Federal de Juiz de Fora (*Física*)

e-mail: radhamscphy@gmail.com

In this work, we deal with glass composition, $29P_2O_5$+(60−□)ZnO+$10Na_2O$+xTeO_2(□=5−40mol.%) doped with 1 mol.% of Nd_2O_3. The samples are characterized by x ray diffraction, micro-Raman, optical absorption, and photoluminescence techniques. Refractive index (□) linearly increased with TeO_2content, as well as the optical basicity (Λ) due to the strengthening of the covalent bond between cation and oxide ions. Such information was corroborated by Raman spectra via an increase of non-bridging oxygens. The maximum phonon energy is approximately 1010cm^{-1}, which is lower than reported for P_2O_5−ZnO−Na_2O phosphate glass (1164cm^{-1}). Detailed spectroscopic and luminescent properties based on TeO_2content are discussed. From luminescence spectra, laser parameters were estimated, viz., radiative transition probabilities, radiative lifetimes, branching ratios, and emission cross sections. The results show that the optimal laser emission parameters are obtained for TeO_2content equal to 20 mol %, which evinces this glass composition as a promising host material for 1.06 µm high-power laser applications.

Effect of the side chain in diketopyrrolopyrrole copolymers: a comparative study between hydrophobic alkyl and hydrophilic triethylene glycol chains

Leonardo Vieira do Prado Cunha[1], Lucas Scalon[2], João Batista Floriano[1], Andreia G Macedo[3], Paula Cristina Rodrigues[1]

e-mail: leonardocunha.2000@alunos.utfpr.edu.br

Organic materials, and particularly conjugated polymers, have played an essential role in optoelectronics. In recent years, considerable attention has been devoted to organic dyes, such as diketopyrrolopyrrole (DPP). In this molecule, changes in the chemical structure can easily modulate their electronic and optical properties. In contrast to the great efforts to develop new conjugated polymer backbones, there are few studies involving the structure-properties correlation of conjugated polymers containing polar side chains, mainly involving electrochemical techniques. In this work, the effect of the DPP side chain (triethylene glycol and hexyl) on the electrochemical properties of a donor-acceptor (D-A) copolymer containing fluorene and DPP units, connected through thiophene rings, has being studied. The cyclic voltammetry technique was further employed to investigate the electrochemical behavior and the stability of the copolymers. For the copolymer with alkyl side chains, four quasi-reversible redox peaks were observed at 1.37 V/1.06 V, 1.56 V/1.34 V, 0.90 V/-0.67 V, and - 1.29 V/-1.16 V (vs NHE), which are associated with the p and n doping. The p-doping/dedoping processes did not show a significant drop in the current peak response of the copolymer even after 410 cycles. By contrast, the reduction process was seen to be quite unstable, and the loss of electrochemical activity occurs already in the 10th cycle of n-doping. Concerning the copolymer with glycol side chain, the preliminary results pointed out a better stability for the p and n doping, probably due to its ability to effectively take up ions from the supporting electrolyte at a relatively fast rate. This electrochemical stability is quite interesting for the application of this polymer as p or n-type material in supercapacitors, smart windows, electrochemical transistors, or even in energy storage devices such as Li-ion batteries.

Effect of WO_3 in the nonlinearities properties oftungsten lead pyrophosphate glasses

Gabriel de Oliveira Campos[1], José Luis Clabel Huaman[2], André Gasparotto Pelosi[2], Danilo Manzani[3], Cleber Renato Mendonca[2]

[1]Instituto de Física de São Carlos - USP (*FCM*) , [2]Instituto de Física de São Carlos - USP, [3]Universidade de São Paulo

e-mail: gabrielcampos@usp.br

Properties such as high chemical stability, photochromism and efficient up conversion [1,2,3], made glasses with phosphate and tungsten matrix potential candidates for optical applications. In this direction, studies with the $NaPO_3$-WO_3 binary vitreous system made it possible to correlate, among other aspects, the increment of tungsten trioxide with the formation of clouds with WO_6 units - highly polarizable, promping the search for compounds with similar structural properties and optimized nonlinear optical responses. In this work, the linear and nonlinear optical responses of the $Pb_2P_2O_7$−WO_3 glass matrix will be characterized due to its structural similarities with the $NaPO_3$-WO_3 system. Yet, the replacement of sodium by a heavier atom results in extended transparency [4] and possibly in higher nonlinearities. For the sample characterization we applied UV-Vis absorption, photoelectron spectroscopy (XPS), and the refractive Z-Scan technique. These techniques make it possible to obtain linear parameters (absorbance, linear refractive index, and chemical conformations) and the dispersion of the nonlinear refractive index, in addition to providing conclusions about the origin of the nonlinear response of the matrix. Finally, high nonlinear refractive responses were observed, paving the way for the use of these compounds in telecommunications and as possible photonic devices.

e-mail: nb.guerra@unesp.br

Bioelectronics combines electronic and biological components in order to develop miniaturized implantable devices capable of altering and controlling electrical signals in the human body. Eumelanin is a natural pigment, biocompatible composed of different structural subunit which can be particularly valuable in the field of bioelectronics because it is a hybrid-type conductor [1]. However, the low conductivity of melanin limits the devices development [2]. In this work, electrochemical doping was proposed to increase the electronic and ionic conductivity of different synthetic melanin derivatives. Melanin films were prepared and electrochemically treated using a three-electrode cell. Different electrochemical parameters were evaluated (scan rate, potential windows and electrolyte concentration). Current-voltage and electrochemical impedance spectroscopy measurements showed that the electronic conductivity of the doped melanin increased when compared to melanins without electrochemical treatment. The experiments were complemented by others chemical characterization techniques, indicating the transfer of species from the electrolyte solution to the melanin film. Our results suggest that electrochemical doping could be an alternative to increase the conductivity of melanin films, allowing its use in the manufacture of organic electrochemical transistors (OECTs).

e-mail: eliezer.oliveira@unesp.br

Diamond surface functionalization has received significant research interest recently due to the impact on the surface electronic structure, which is of interest in engineering diamond as a semiconductor. To understand the modifications on diamond surface electronic structure caused from sulfur and nitrogen groups, we performed Density Functional Theory (DFT) simulations using a PAW/GGA approach [1], as implemented in the computational code Quantum Espresso (QE) [2]. We explored 6 different surface coverage: 100%H, 91%H/9%S, 92%H/8%NH_2, 83%H/9%S/8%NH_2, 74%H/18%S/8%NH_2, and 75%H/9%S/16%NH_2. Our results indicate that the diamond surface functionalized with S or/and NH_2presents a lower the bandgap in comparison to the 100%H, which is caused by the electronic levels that came from S and N atoms. The S atoms produces a new conducting band minimum lower than that observed for the 100%H, and the N atom could increase slightly the valence band maximum. The best results for the bandgap energy are seen for the 75%H/9%S/16%NH_2surface coverage, once the S atom keep the conducting band minimum lower than that for 100%H and the percentage of NH_2higher than S can affect the valence band maximum increasing it in energy, resulting in a decreased bandgap. The results show that the S determine the conducting band minimum, but It is important to keep the percentage of NH_2higher than S on the surface to guarantee the increasement of valence band maximum, since the S could keep it lower.

Energy transfer processes in BBPT glasses doped with Nd^{3+}

Ilza Tenório Cavalcante Santos[1], Maria Jose Valenzuela Bell[1], Virgílio de Carvalho dos Anjos[1]

[1]Grupo de Engenharia e Espectroscopia de Materiais (*Departamento de Física, Universidade Federal de Juiz de Fora - MG, Brazil*)

e-mail: ilzafisica@gmail.com

Solid-state lasers operating in the visible and near-infrared (NIR) regions are currently in focus due to their potential applications in technology, telecommunications, sensors, defense and diagnostics in medicine. In the present work, we analyzed boroteluride glasses (B_2O_3+Bi_2O_3+PbO+TeO_2) doped with Nd^{3+}ions, prepared by cooling melting and characterized by optical absorption techniques (UV-Vis-NIR-MIR), near infrared emission. The decay of Nd^{3+}: $^4F_{3/2}$were characterized by Judd-Ofelt parameters (Ω_λ, $\lambda = 2$, 4 and 6), radiative transition probabilities (A_{rad}), radiative lifetimes (τ_{rad}) and branching ratios (β). The Judd-Ofelt parameters were obtained from the emission and absorption spectra. With these parameters, it was observed that the matrix did not undergo a significant change as a function of the concentration of 0.5Nd^{3+}ions.

Engineering nano and natural-form of conjugated copolymer thin films with silver nanoparticles: structural and morphological studies

Rebeca da Rocha Rodrigues[1], Diogo Silva Pellosi[1], Guy LOUARN[2], Laura Oliveira Péres[1]

[1]Universidade Federal de São Paulo (*Química*) , [2]Institut des Matériaux de Nantes JeanRouxel

e-mail: rebecar.rodrigues@hotmail.com

The electrical, thermal, and optical properties of conjugated polymers (CPs) and metallic nanoparticles make them interesting components in the development of devices, because of the formation of nanocomposites with improved properties [1]. However, the hydrophobicity property of CPs can hinder their application in aqueous media. Recent studies demonstrated that this can be overcome by the formation of CPs nanoparticles in aqueous media [2]. Thus, this work characterizes the morphological and structural properties by AFM, XPS and Raman spectroscopy of thin films composed of the copolymer poly(9,9-dioctylfluorene-co-3,4-ethylene dioxythiophene) (PDOF-co-PEDOT) in its nanoparticle (NCP) and natural form, combined with silver nanoparticles (AgNP) of different morphologies (spherical and triangular), aiming further application of these nanocomposite films as SERS-active layers for pesticide sensors. AFM images of NCP/AgNP films showed specific structures that were transferred to the solid substrate. The films' morphology could also be influenced by the geometry of AgNP. XPS data demonstrated that the insertion of the AgNP can result in the oxidation of the polymeric chains, but the discovery that NCP films are more resistant to this type of degradation makes this material more interesting for future applications. Raman spectra showed the enhancement effect of polymer Raman bands, indicating the SERS effect induced by the AgNP. Due to these interesting properties, these specific films can be promising in future applications as SERS sensors, as well as in applications where degradation processes are important to be considered.

In this work, a solvent vapor annealing procedure (SVA) was used to improve the optical and adhesion features of a conjugated copolymer:molecule acceptor film. The power dissipation was simulated along the structure of organic photovoltaic device devices considering the interference occurring in stacked thin films under normal incidence by using the transfer matrix method (TMM). Therefore, the monitoring through ellipsometry and TMM modelling contribute to understand the behavior of the electromagnetic wave inside the device, providing insights about proper optimizations that can be performed to increase the G(x) rate and the Jsc parameter. This model takes into count the experimental values of refractive index n and extinction coefficient k acquired from the D:A film to simulate the spatial distribution of the electric field and provide valuable information about photovoltaic parameters. The results pointed out that the SVA-treated films presented distinct refraction index curve, as well as improved electric field distribution, when compared with cast films.

Evaluation of stability and bioactivity of a nanocomposite formed by conjugated polymer andsilver nanoparticles

One of the great advantages of mixing components in a single system, in addition to using smaller amounts of samples, is that the properties arising from the isolated materials are gathered in a single final product [1]. In this scenario, we propose the combination of conjugated copolymer nanoparticles (CPN) composed of poly(fluorene/thiophene) with spherical silver nanoparticles (AgNP) in different proportions (v/v) (CPN:AgNP_1:5, 1:3, 1:1 and 3:1) aiming to obtain a stable nanocomposite with bioactivity against microorganisms such as bacteria. Therefore, aqueous dispersions of both materials were prepared and analyzed by UV-Vis absorption spectroscopy, fluorescence, dynamic light scattering (DLS), and zeta potential, in order to evaluate the samples stability, during three weeks after preparation. All samples demonstrated stability for at least two weeks. Two samples in different ratio (CPN:AgNP_1:3 and 3:1), as well as the isolated components, were selected for minimum inhibitory concentration (MIC) analysis, against the bacterial Escherichia coli and Staphylococcus aureus. The bioassay results showed enhanced bioactivity in the composites compared to those of prevenient from metallic silver nanoparticles or CPN alone. Prominent results were obtained using the nanocomposite CPN:AgNP_1:3. In this sense, it was possible to conclude that nanocomposite preparation could efficiently improve nanocomposite stability and microbicide properties, which augurs well for further developments of CPN/AgNP microbicide materials.

Evaluation of the Structure-Property of Thin Films of Polyaniline-based Nanocomposites with Metal Oxides Deposited via Spin Coating

Amanda Portes Vieira[1], Hugo José Nogueira Pedroza Dias Mello[2]

[1]Universidade Federal de Goiás (*Instituto de Física*) , [2]Universidade Federal de Goiás

e-mail: amandaportes@discente.ufg.br

Polyaniline (PANI) has a special position in the field of conducting polymers due to its simple and low cost synthesis, high conductivity and stability, deposition as thin film and special proton doping mechanism. Thereby, this polymer is a candidate for many applications, such as capacitors, chemical, gas and biological sensors [1]. PANI properties can be shaped upon exposure to acids and bases, and when incorporated with different materials like metal oxides. Its combination with metal oxides presented promising results for electrochemical sensor applications. As shown in our previous work [2], combining PANI with metal oxides improved the sensor''s performance in linearity and sensitivity. The present work pursues improving the previous approach and seeks to produce low-cost electrochemical pH sensors using thin nanocomposites films of PANI and metal oxides. We use PANI/CeO2 and PANI/WO3 nanocomposites, deposited via spin coating. The films were produced using a PANI dispersion and a metal oxide (CeO_2or WO_3) solution, both in N-methyl-2-pyrrolidone (NMP, 99%) mixed in five different proportions (90/10, 70/30, 50/50, 30/70, 10/90, V/V) [3]. The films of PANI/$CeO_2$and PANI/WO_3were applied in the electrochemical impedance and capacitance spectroscopy (EIS and ECS) transduction stages as pH sensors, and characterized by their thickness and roughness, UV-VIS absorbance spectra. The structure-property relationship of the nanocomposite thin films is dependent on the proportion of its constituents and directly influences the sensor's response.

Crystallography is a broad area of study that incorporates studies of organic and inorganic materials of biological interest. This work studied the crystal of adenosine hydrochloride (AC). AC crystals were grown, characterized by X-ray diffraction (XRD), differential scanning calorimetry (DSC) and Raman spectroscopy, Hirshfeld surface and their vibrational Raman spectra were calculated and compared to the experimental, in addition to the frontier molecular orbitals. XRD data refined by the Rietveld method show that the crystal belongs to the monoclinic system, P21-space group, and lattice parameters with values similar to the literature [1]. In the DSC analysis, it was identified that no thermal event occurs before the melting of the material, which occurs around 145 ºC. Hirshfeld surface analysis shows the crystal packing interactions and their importance, as well as the relative amounts of each interaction in the 2D fingerprint. The calculated geometric data showed a lot of similarity with the experimental data, as well as the Raman spectra showed good agreement between theoretical and experimental results. The gap energy (Egap) was 5.47 eV, with the border orbitals present in greater density in the adenine portion of the AC molecule, with an evident difference in the chlorine atom, fully occupied by electronic density in HOMO. Egap value of the AC molecule was higher when compared to 5mU, showing that AC is probably less reactive than 5mU [2], as shown by chemical hardness.

Field-effect sensor based on $CoFe_2O_4$ nanocrystals and graphene oxide as a sensitive layer for environmental applications

Paulo Vitor de Morais[1], Michael Josef Schöning[2], José Roberto Siqueira Junior[1]

[1]Universidade Federal do Triângulo Mineiro (*Departamento de Física*), [2]INB (*Institute of Nano- and Biotechnologies*)

e-mail: paulo_vitor_d_morais@hotmail.com

Sensor devices have shown significant potential in portable microelectronic systems for biomedical and environmental applications. To obtain sensing units with superior properties and performance, it is crucial to study (nano)materials and their optimal integration in the device as a receptor layer for the target analyte [1]. In this context, cobalt ferrite ($CoFe_2O_4$) has been reported as an attractive material for H_2O_2 catalysis, as well as graphene oxide (GO), which has unique properties for H_2O_2 detection and heavy metal adsorption [2]. This study was aimed at investigating the effect of layer-by-layer (LbL) films containing $CoFe_2O_4$ nanocrystals embedded in PAH and GO as a receptor layer (sensing unit) on an electrolyte-insulator-semiconductor (EIS) field-effect sensor platform. LbL films with PAH-$CoFe_2O_4$/GO structure were applied to detect H_2O_2, Cd^{2+}, and Cu^{2+} ions, envisaging a proof-of-concept field-effect sensor for environmental applications. Scanning electron microscopy (SEM) revealed a LbL film morphology with high surface area featuring heterogeneous clusters of nanocrystals covered by a homogeneous GO coating. Electrochemical characterizations were carried out by capacitance-voltage (C/V) and constant-capacitance (ConCap) measurements demonstrating catalytic characteristics in detection experiments of an optimized EIS-LbL sensor containing 6 bilayers. This sensor system was sensitive and exhibited a low limit of detection of ca. 314 µM for H_2O_2 and 0.54 µM and 0.47 µM for Cd^{2+} and Cu^{2+} ions, respectively. These results prove the relevance of the PAH-$CoFe_2O_4$/GO structure as a receptor layer in EIS devices for environmental applications.

Fluorescent polymer films based on thiophene and fluorene with electrochromic properties

Vitória Rocha de Oliveira[1], Fred Augusto Ribeiro Nogueira[2], Eleine Batinga Rodrigues Torres[3], Johnnatan Duarte de Freitas[2], Adriana Santos Ribeiro[3]

[1]Universidade Federal de Alagoas (*Instituto de Química e Biotecnologia*) , [2]Instituto Federal de Educação, Ciência e Tecnologia de Alagoas, [3]Universidade Federal de Alagoas

e-mail: vitoria.oliveira@iqb.ufal.br

Conjugated polymers have attracted broad academic and industrial interest due to their applications in polymer light-emitting diodes, polymer solar cells, electrochromic devices and fluorescent sensors. Recently, multifunctional stimuli-responsive optical materials showing electrochemical switching of both coloration and emission based on conjugated polymers have been synthed through incorporation of electroactive fluorophores into the polymer main chain and their properties have been investigated aiming at application in electro-optical devices [1]. Fluorene and polyfluorene derivatives have a rigid planar structure, excellent hole-transporting properties, chemical stability and photoluminescence efficiencies. Thus, the preparation of extended π-conjugated systems based on the introduction of a fluorene bridge into the bisthiophene main chain can render multifunctional materials that exhibit both electrochromic and fluorescent properties. Herein a p-extended system based on thiophene and fluorene, named 2,2’-(9,9-dioctyl-9H-fluorene-2,7-diyl)bisthiophene (FBT), was electrodeposited on Indium Tin Oxide (ITO) electrodes at relatively low potential and the electrochromic properties of its polymer films (PFBT) were investigated. The changes in the spectral absorption bands according to the potential applied to the system were interpreted by using the CIE 1931 xy chromaticity coordinates. The colors of the polymer film change from yellow in the neutral state (E = 0.00 V) to green in the oxidized state (E = 0.85 V). Simultaneously, the PFBT films are fluorescent in the neutral state and the emission is quenched at anodic potentials. Thus, the high electrochromic and fluorescence contrast of the PFBT films according to their oxidation states makes them suitable for application in multifunctional optical devices, such as electrofluorescent devices.

Functionalized hybrid materials for photonics and biological systems

Adriano José Galvani Otuka[1], Debora Terezia Balogh[2], Cleber Renato Mendonca[2], Alexandre Mesquita[1], Fabio Simões de Vicente[1]

[1]São Paulo State University (*Physics Department*) , [2]University of São Paulo (*São Carlos Institute of Physics*)

e-mail: adriano.otuka@unesp.br

Functionalized hybrid materials have unique physicochemical properties and currently are employed in several technological fields, since optics and photonics, until biomedical applications. For instance, a hybrid matrix functionalized with optically active compounds allows potential materials for RGB-devices fabrication or random laser systems, due to their convenient optical and morphological characteristics. Additionally, such matrices allow the fabrication of specific photonic devices with nonlinear responses, such as optical limiters. Regarding biomedical applications, hybrid materials can be sculpted using high intensity lasers and miniaturized devices can be produced for desired systems. In this context, the present work shows the synthesis of hybrid matrices functionalized with different optically active compounds, such as organic dyes, lanthanide complexes, semiconductor nanoparticles or crystalline forms of Carbon, in order to produce samples for photonics experiments. The mixture of a silane compound and acrylate monomers composes the host matrix. Using these functionalized matrices, we produced thin films and bulks, obtaining structures like *xerogel* or *aerogel*. Such samples presented structures with thermal stability and high mechanical resistance, among other interesting features for prospect applications. We characterized the prepared samples using several methodologies, such as optical spectroscopy, photoluminescence and electron microscopy. Finally, we also fabricate miniaturized devices using direct laser writing (DLW) technique, which employ femtosecond lasers, with high intensity pulses. The fabricated devices have micrometer resolution and are potential structures for photonics and biological applications.

Immobilization of graphene oxide and laccase on lipid Langmuir-Blodgett films: possible application for biosensors for phenolic compounds

Felipe Merloto Marinho[1], José Siqueira Júnior[2], Luciano Caseli[3] [1]Departamento de Biofísica, Escola Paulista de Medicina, Universidade Federal de São Paulo (*Department of Chemistry*) , [2]Universidade Federal do Triângulo Mineiro, [3]Universidade Federal de São Paulo (*Department of Chemistry*)

e-mail: fmmarinho22@unifesp.br

Inserting graphene oxide in Langmuir-Blodgett (LB) films of enzymes confined in lipids can improve their catalytic performance, which is interesting for bioelectronics since robust biosensors can be assembled. In this work, we incorporated the enzyme laccase and graphene oxide from the aqueous subphase in 1,2-dimyristoyl-sn-glycero-3-phosphatic acid (DMPA) Langmuir monolayers and transferred them to solid supports as LB films to essay the catalytic activity towards the oxidation of a variety of phenolic substrates, performing the electronic transfer. Surface pressure-area isotherms, polarization-modulated infrared reflection-absorption spectroscopy, and Brewster angle microscopy characterized the floating monolayers. The adsorption of the enzyme at the air-water interface condensed the lipid monolayer, altering the film compressibility at high surface pressures. The monolayers were transferred to solid supports as LB films and characterized with fluorescence spectroscopy and quartz crystal microbalance. Viability as sensors was tested with UV-vis spectroscopy. We believe that the enzyme accommodated in the DMPA LB films preserves the catalytic activity, and graphene oxide helped conserve the catalytic properties for more extended periods of storage. The method presented in this work allows for controlled catalytic activity and can help explain why specific film architectures exhibit improved performance.

e-mail: miriam.kezia@ufpe.br

Triboluminescent materials, such as crystals of europium complexes, convert mechanical energy into visible light, making them attractive for potential applications in the development of real-time structural damage sensors [1]. Preparation methods have been shown to have a significant impact on the triboluminescence properties. For example, when [Eu(DBM)$_3$(TPPO)$_2$] was prepared by a conventional heating synthetic methodology, as it has already been reported in the literature, apparently that led to no triboluminescence [2]. In this work, we demonstrate that the use of microwave-assisted syntheses can lead to triboluminescent crystals of europium complexes with β-diketonate ligands. The microwave reactor heating is uniform and impacts the crystallization of these compounds. Accordingly, we prepared the ternary europium (III) complexes [Eu(β)$_3$(TPPO)$_2$] and [Eu(Cl)(β)$_2$(Phen)$_2$] with the ionic β-diketonate ligands (β = DBM, BTFA, TTA, TFA, HFAC) and the non-ionicligands TPPO (triphenylphosphine oxide) and Phen (1,10-phenanthroline). The optimizedsynthetic conditions were 100 W, 75 °C during 10 minutes for each reaction step. Theproducts were characterized by FTIR and NMR (^{1}H and ^{19}F) spectroscopies. As a result, all these ternary complexes were found to exhibit luminescence upon mechanical stress (rubbing), confirmed by acquiring their triboluminescence spectra, which showed transitions that are typical of the europium ion. Based on our findings, we conclude thatutilization of the microwave-assisted method for the preparation of triboluminescent materials has significant potential for further development of more responsive smart materials and structural damage sensors.

e-mail: julia.akiyama@usp.br

Porphyrin's molecular structure confers the ability to efficiently generate singlet oxygen, which is the primary cytotoxic agent responsible for the elimination of cancer cells, and this efficiency is related to the formation of molecules at the triplet long lifetime excited state. Organic molecules exhibiting nonlinear optical responses have key advantages because of their potentially increasing depth of light penetration in tissue. In this work, to complement the triplet study, we report on the study of two-photon absorption (TPA) spectra of a series of tetraphenyl porphyrin with chalcone derivatives groups in its neutral and cationic forms. It was expected that the electronic nature of porphyrins leads to a significant change in two-photon absorption cross-sections due to different electron-accepting groups and symmetry changes, influencing the TPA magnitude with distinct chalcone derivatives, which is extremely important in applications such as fluorescent bioprobes. In this way, the two-photon absorption cross section peaks exhibited values in the range of 15 GM in porphyrin'sQ bands, which is a terapeutic window, interesting for biological applications and not so much found in literature.

As it is known, so far, in the literature a few works report measurements on TPA cross-sections in porphyrins molecules, which is known to be difficult because of the easy aggregation of those at low molar concentrations. Thus, to circumvent this problem, we have set up a technique based on monitoring the fluorescence induced by a two-photon absorption that can be used for solutions at very low concentrations, avoiding aggregation.

Investigation of nanostructured films containing PAMAM, reduced graphene oxide and tungsten oxide for application in supercapacitors

Vanderley Ferreira Gomes Junior[1], Danilo Alves Oliveira[2], José Roberto Siqueira Junior[1]

[1]Universidade Federal do Triângulo Mineiro, [2]Universidade Federal do Triângulo Mineiro (*Departamento de química*)

e-mail: junior.0788@hotmail.com

Supercapacitors are energy storage devices that have attracted attention of researchers due to their unique characteristics, including as high power density, fast charge and discharge rates and long lifetime [1,2]. Different combinations of materials and different ways of arranging them have been the focus of research in recent decades. In this study, we investigated the combination of poly(amidoamine) (PAMAM), reduced graphene oxide (rGO) and tungsten oxide (WO3) as nanostructured films assembled on conductive substrates of indium tin oxide (ITO) as a supercapacitor electrode for energy storage application. Using the layer-by-layer technique, multilayer films with high capacitance values were found for films containing 20 bilayers. Cyclic voltammetry revealed an areal capacitance of ca. 6.5 mF/cm² at a scan rate of 1 mV/s. The galvanostatic charge-discharge characterization pointed to a discharge time of ca. 300 s at a current of 3 µA, which permited reaching aspecific capacitance value of 75 F/g, with an energy density of 5 Wh/kg and a power densityof 60.6 W/kg. The latter values compared with blank control electrodes without WO3 exhibited capacitance and energy and power densities 2.5 times lower, demonstrating thatthe presence of WO3 was essential to achieve a supercapacitor with improved performance. These findings prove that nanostructured films based on rGO-WO3 can be employed andexpanded for supercapacitors applications.

Photoinduced charge separating molecular systems are often key players in clean energy generation, such as organic photovoltaic devices.[1] We investigated π-junctions of N,N'-bis(3-triethoxysilylpropyl)-1,4,5,8-naphthalenediimide (NDI-silane) with 3,7-di-t-butylphenothiazine (TBP) as donor (D) - acceptor (A) system for photoinduced charge separation. From Time-Dependent Density Functional Theory (TD-DFT) calculations with optimized hybrid functionalization (OT-RSH), we observed in the NDI-TBP dimer and the NDI-TBP multimolecular configuration an alignment of the HOMO and LUMO eigenvalues of the molecules, in a "cascade fashion". As a consequence, the NDI TBP-dimer and a multimolecular configuration show excited states with a strong charge transfer character, around 1,4 eV (O.S ≈ 0.015) and 1,0 eV (O.S ≈ 0.013), respectively. In the experimental study, we first derived a methodology to obtain pure and stable crystals of NDI-silane from crystallization in petroleum ether and ethyl ether with a net yield of 10%,[2] confirmed by liquid state ^{1}H, ^{13}C and ^{29}Si nuclear magnetic resonance spectroscopy. This precursor was used to prepare NDI-silane and a 1:1 v/v NDI-TBP thin films by spin coating. They were characterized by optical and atomic microscopy, profilometry, absorption spectroscopy, and photoconductivity. The films were obtained with high homogeneity and an optimal thickness of 300-500 nm, demonstrating significant absorbance in the UV and blue spectral region, and a measurable photo-conductivity effect. In conclusion, it was noted that the NDI-TBP heterojunction demonstrates great potential to be applied as photoinduced charge-separating systems.

Usually, electronic tongues (e-tongue) do not require specific interactions to discriminate aqueous solutions. Among the several factors which determine the electrical properties of sensorial units, the interactions between liquids and interfaces have a crucial role. Here, we explore the interaction between dioctadecyldimethylammonium bromide (DODAB) lipid and carbendazim (MBC) pesticide in an e-tongue to discriminate different MBC concentrations in aqueous solutions. The sensorial units were fabricated of gold interdigitated electrodes (IDEs) coated with Layer-by-Layer (LbL) films of DODAB and nickel tetrasulfonatedphthalocyanine (NiTsPc), perylene and 1,2-dipalmitoyl-sn-glycero-3-phospho-(1''-rac-glycerol) (DPPG), namely DODAB/NiTsPc and Perylene/DPPG, respectively. Besides a bare electrode also constituted the e-tongue to distinguish MBC concentrations from 1.0 x 10^{-7} up to 1.0 x 10^{-10} mol L-1, by impedance spectroscopy. The LbL films were manually fabricated obtaining linear growth monitored via UV-Vis absorption spectroscopy. Optical images associated with chemical mapping reveals the presence of small aggregates in the DODAB/NiTsPc LbL film surface. Although the e-tongue was able to discriminate all MBC concentrations by means interactive document map (IDMAP), only the sensorial unit covered with DODAB/NiTsPc LbL film presents satisfactory response. According to the equivalent circuit the main contribution arises from the bulk and film surface due to the interaction between DODAB and MBC indicating selectivity of the sensorial unit. Finally, the adsorption of MBC molecules onto the film surface induced an irreversible process, although there are some frequencies which the sensorial unit response seems to be reversible, as shown by parallel coordinates.

L-Tyrosine Methyl Ester Hydrochloride under high-pressure

Amino acids N-methylation has been used in synthesis of new peptide-based drugs by pharmaceutical industry [1]. N-methylation has the ability to change hydrogen bonds configuration and molecular conformation of peptide chain, altering their biological functions [1]. Here, we purpose to investigate the vibrational and structural properties of L-Tyrosine Methyl Ester Hydrochloride crystal (LTMEHCl) by high-pressure Raman Spectroscopy. LTMEHCl was grown by slow evaporation method (stirring for 3 h, at 200 rpm and 318 K; pH = 2.15), over a period of 3 months. Powder X-ray diffraction was performed on Empyrean powder diffractometer of the Panalytical (Cu Kα radiation, λ = 1,5418 Å), with 0.02° and 2 s/step in 5-50° 2θ range. High-pressure Raman scattering (1 atm - 9.0 GPa), in a T64000 Jobin Yvon spectrometer, using LTMEHCl and Nujol oil, wasperformed. Laser beam (Ar: Kr laser, k = 514.5 nm, backscattering geometry) was focusedwith Olympus BH40 microscope. LTMEHCl was obtained in monoclinic symmetry. High- pressure Raman results revealed reversible spectral changes in the pressure range of 0.3 -1.3 GPa and 2.8-5.0 GPa, indicating, at least, conformational phase transitions. Notably, methylation increase the flexibility of the LTMEHCl crystal lattice compared to L-tyrosine hydrochloride, which did not exhibit any phase transitions in similar conditions [2].

Luminescent membranes based on derivative celulose acetate butyrate (CAB) doped with europium complex

Celso Molina[1], Ana Luisa Moreira Arrozio[2]

[1]Federal University of Sao Paulo (*Chemistry*) , [2]Federal University of Sao Paulo

e-mail: cmolina@unifesp.br

Polymers based on cellulose derivative have been attracting interest considering a sustainable approach. Cellulose Acetate Butyrate (CAB) presentes interesting properties such as film forming, flexibility, high transparence in the visible range. Its solubility in a wide variety of solvents make it useful as an additive in coating compositions. It has been applied as diffuser layer to suppression of the viewing angle dependence on blue OLEDs [1]. Considering these properties CAB arises as potential matrix for immobilization of lanthanides for luminescente applications. In this work, [Eu(tta)3(H2O)2] was incorporated, 0.2 to 3.2% (w:w), in the Eastman CAB-551-0.2 (Butyryl 52wt, Acetyl 2wt and Hydroxyl 1.8% content) Mw 30000 by using ethyl acetate as a solvent. Membranes of CAB-[Eu(tta)3(H2O)2] were synthed by casting and characterized by FTIR-ATR, UV-Vis, TGA and Photoluminescence. Membranes present high transparence in the visible range, flexibility and a broad band in the UV region with maxima at 270 and 340 nm assigned to π-π* excited states of ligand. FTIR-ATR show that complex was well dispersed in the CAB matrix. In addition, the membranes are thermally stable up to approximately 300oC. Excitation spectra monitored at 614 nm (5D0 → 7F2) show a broad band in the UV region with maximum peak shifted to higher energy as a function of complex content. Emission spectra display high intense sharp lines ascribed to 5D0 → 7F0-4 transitions through the antenna affect [2]. CIE diagram show (0.68, 0.32) color coordinates and decay curve, fitted by a single exponential exhibit experimental lifetime of 0.32 ms. The same behavior was observed for all composition studied. suggesting only one Eu3+ local site. The synergism between CAB and complex present potential application for flexible emitting luminescent devices.

All-optical photonic devices are currently widely investigated as they allow to improve the overall circuit speed which is limited by response time of electronic devices. Advances have being made in this regard, such as the development of optoelectronic devices for integrated circuits [1,2]. This work investigates the structural and non-linear properties of microstructures printed by thermal poling on glass $65GeO_2-20Nb_2O_5-15Na_2O$. Thermal polling was performed using an anode with Pt film deposited with microstructures design forming 40 μm wide squares. The poling system was heated to 265oC for 30 minutes at N_2 atmosphere and a DC bias of 1200 V was applied.

AFM analysis allowed to characterize the morphology of the subanodic surface which presented a depth of about 150 nm. PHASICS data were used to calculate the variation of the refractive index $\Delta n = n(NIC) - n(IC) = -0.085$, where NIC and IC are the regions non in contact and in contact with the conductive electrode. The increase in the index of refraction in the IC region is due to the network polymerization and the higher content of NbO_6 polyhedra. Nonlinear optical analysis were recorded by μ-SHG polarized microscopy and show well localized SHG signals at the edges of the square. This microdevice may besuitable for photonic applications, especially wavelength conversion and electro-optical devices.

In the manufacture of optoelectronics, various commercial techniques are used, such as roll-to-roll printing, screen printing, inkjet printing, foil coating, gravure printing, flexography, spray coating and brush painting. However, each of these techniques has specific disadvantages, such as high temperature heat treatments, application of toxic solvents and disposal of contaminated waste. On the other hand, electrospinning is a promising technique for the production of polymeric fibers on a large scale, with advantages such as versatility, high surface/volume ratio, unidirectional conduction, low cost and environmental sustainability. In addition, electrospinning allows the nanoscale modification of the structural characteristics of optoelectronic components, arousing great interest in the scientific community. Reduced graphene oxide (rGO) is a suitable material for use in flexible conductive electrodes, transparent and stretchable, due to their high conductivity and mechanical resistance, which help in the efficient transport and capture of charges from the active layer to the device. In this job, Poly(vinylidene fluoride) (PVDF) and rGO polymeric fibers were electrospun at different concentrations and characterized by techniques such as optical microscopy, scanning electron microscopy and Fourier transform infrared spectroscopy, with the aim of being used in optoelectronic devices.

New heterodyne Z-scan technique to measure thethermal and Kerr nonlinearity of materials

Renato Mafra Moysés[1], Emerson Cristiano Barbano[2], Lino Misoguti[1]

[1]Instituto de Física de São Carlos - USP (*Photonics Group*) , [2]Universidade Federal do Paraná (*Physics Department*)

e-mail: renatomaframoyses@usp.br

Heterodyne Z-scan technique (HZS) was designed to measure slow nonlinear refraction of materials employing CW laser and dual phase lock-in [1]. In order to do the heterodyne detection, the original setup uses an unusual sinusoidal intensity modulator. Now, by replacing this modulator with a simple optical chopper, we could extend the use of HZS method with ultrashort pulses. In this case, we can measure both the thermal and ultrafast Kerr nonlinear effects. Basically, the dual-phase lock-in detects the pure thermal and the combination of both effects in the Phase and Magnitude signals, respectively. Also, by measuring HZS as a function of chopper repetition rate, it is possible to find the response time of the thermal nonlinearity. Here, we proposed to perform the HZS measurements to discriminate the thermal and Kerr nonlinearity of different materials. We characterized pure CS_2 solvent using ultrafast laser pulses (Carbide, Light Conversion, ~200 fs at 515 nm, 1-1000 kHz repetition rate). This laser is interesting since the thermal lens signal can be controlled by its repetition rate. CS_2 is a well-known material with high Kerr nonlinearity with two-photon absorption thermal lens when high-repetition rate laser is employed. Moreover, linear and circular polarization can discriminate the pure electronic and molecular orientation effects from the effective Kerr nonlinearity [2]. Optical glasses were also characterized.

Nonlinear properties and structural rearrangements in thermally poled niobium germanate glasses

Lia Mara Silva Marcondes[1], Juliane Resges Orives[1], Thierry Cardinal[2], Marc Dussauze[3], Marcelo Nalin[1]

[1]Universidade Estadual Paulista (*Institut of Chemistry*), [2]Université Bordeaux 1 (*ICMCB*), [3]Université Bordeaux 1 (*ISM*)

e-mail: lia-marcondes@hotmail.com

Research on glass materials has gained prominence since adjusting the composition/properties of glasses can result in greater material efficiency. Glasses containing transition metal elements are known to exhibit enhanced luminescent properties of rare-earth ions [1], as well as nonlinear optical (NLO) properties [2]. This work encompasses the structural and NLO characterizations resulting thermal poling in sodium niobium germanate glasses: $(100-x)GeO_2-xNb_2O_5-15Na_2O$ with x = 15, 20 and 25mol%. Thermal poling was also performed for 30 min, at ~265 oC and a DC bias of 1200 V.

A subanionic layer was formed in the region in contact with the conductive homogeneous electrode. Structural rearrangements and nonlinear properties were investigated by micro-Raman and micro-SHG. Sodium depletion and a static electric field implementation occur in the subanionic layer. Structural rearrangements occurs due to decrease in non-binding oxygen (NBO) bonds and O_2 generation due to recombination NBO atoms leading to the release of sodium and oxide ions in the NLO layer. Macro-SHG response was quantified using the Maker fringes technique and the electric field induced second harmonic (EFISH) model was used to simulate the fit and determine the $\chi 2$ susceptibility. The $\chi 2$ values showan increase from 0.42 to 0.76 pm/V with the niobium content.

Nonvolatile memory devices with anodized aluminum layer

Maria Leticia Vega[1], Jayane Oliveira Borges[1], Yasmim Mayra Sales dos Santos[1], Helder Nunes da Cunha[1], Alexandre de Castro Maciel[1], Ángel Alberto Hidalgo[1]

[1]Universidade Federal do Piauí (*Física*)

e-mail: marialeticia.vega@ufpi.edu.br

Non-volatile metal oxide memory devices are of great interest in the field of information storage. These materials have specific physical properties such as high resistivity and permeability, in addition to transparency over a wide range of wavelengths. In memories, the oxide layer acts as a tunneling barrier between the different layers that make up the device, allowing the storage of electrical charges [1-2]. Film properties depend strongly on the synthesis and/or deposition process. The anodizing is a lower cost alternative, as it does not require a controlled atmosphere. Anodizing is an electrochemical process that involves the controlled oxidation of the metal through a redox reaction, generating a thickening of the oxide layer on the surface of the material. In this work, we performed the deposition of aluminum films on a glass substrate that received the anodizing treatment to grow the native oxide layer. Different voltages and application time and, consequently, current, were used. For electrolyte solution, H_3PO_4 at 0.4mol L^{-1} was used and platinum electrode as cathode. It was observed that increasing the aluminum oxide layer generates an increase in film transparency. The increase in the oxide layer increase transmittance, and consequentlya decrease in the absorbance. We observed dependence between time and voltage appliedin the experiment, with oxide growth being directly proportional. Roughness increases with increasing exposure time. The resultant memory devices with Al/Al_2O_3/MEH-PPV/Al architecture were characterized and showed bipolar behaviour. After electroforming the device show two distinct resistance states: Low Resistance (LRS) and High Resistance States (HRS). Current ratio between LRS and HRS is at least 10^3. Long term retention and endurance cycling are in progress.

One-pot synthesis of pinacolone derivatives from acetophenones

Andréia Joice Oliveira Meira[1], Thiago Branquinho de Queiroz[1], Alvaro Takeo Omori[1]

[1]Universidade Federal do ABC (*Centro de Ciências Naturais e Humanas*)

e-mail: andreia.meira@aluno.ufabc.edu.br

During the investigation to synthe 3,7-di-t-butylphenothiazine (a potential good π-electron donor for photoinduced charge separation process) from phenothiazine by using zinc and tert-butyl chloride as reagents,[1] we observed that these conditions led to the formation of 3,3-Diphenyl-2-butanone (a pinacolone derivative) in a one-pot, single step fashion, starting from commercial acetophenone. According to the literature, the synthesis of pinacolone derivatives directly from acetophenones is not well reported. To assess the scope of the methodology, different acetophenones were tested and the corresponding pinacolones were obtained in moderate yields. Structure elucidation was supported by ^{1}H, ^{13}C NMR spectra and GC-MS (gas chromatography-mass spectrometry) and showed a high degree of purity. This methodology can be useful in materials science since some pinacolone derivatives have applications as radical initiators in polymer synthesis.[2]

Environmental concerns reinforce the relevance of clean and viable renewable energy sources. Due to its abundant energy resource available and lower production costs, solar energy is one of the best options. Organic photovoltaic devices (OPVs) are made of organic (carbon-based) semiconducting small molecules or polymers for converting incident sunlight into electrical power [1]. Photovoltaic cells generate electricity directly via the photovoltaic effect. In this work, the OPVs were built in the FTO/PEDOT:PSS/P3HT/Al, FTO/PEDOT:PSS:GO/P3HT/Al and FTO/PEDOT:PSS/P3HT:PCBM/Al device architecture. We performed current-voltage measurements in temperatures ranging from 80 to 300 K. We also carried out on the parameters that define its electrical properties, such as the lifetime of photogenerated carriers and its electronic mobility.

Photophysical and electrochemical properties of three novel fluorescent Benzazole derivatives and their interaction with fullerenes

Cristian Alvarez Guaje[1], Abad Roger Castillo Hinojosa[2], Bruna Bueno Postacchini[1], André A. Vieira[2], Thiago Cazati[1]

[1]Universidade Federal de Ouro Preto (*Departamento de Física*) , [2]Universidade Federal da Bahia (*Instituto de Química*)

e-mail: cristian.guaje@aluno.ufop.edu.br

Here, we present the study of the photophysical and electrochemical properties of three novel fluorescent Benzazole derivatives, constituted by a central sulfur heteroatom, or oxygen or nitrogen and their interaction with fullerenes in solution. The photophysical properties were studied in liquid (solution) and solid (film) state at room temperature using absorption, stationary fluorescence and time-resolved fluorescence spectroscopy. The molecules exhibited absorption in the visible region, high fluorescence quantum efficiencies, and monoexponential (a single excited state lifetime) fluorescent decays. The energy values of the molecular orbitals (HOMO, LUMO) of the molecules were estimated using voltammetry (VC). The fluorescence intensities of the compounds in toluene solution with different concentrations of fullerenes C60 and derivative Pyrrolidine tris-acid ethyl ester (PyC60) were quenched by simultaneous mechanisms (dynamic and static) of fluorescence quenching. The fluorescence suppression constant (Ksv) and the radio of the effective suppression spheres were obtained from Stern-Volmer plots. The three novel fluorescent Benzazole derivatives presented optoelectronic characteristics suitable for their application in organic electronic devices, specially for solar energy conversion.

Benzochalcogendiazole heterocycles have been identified as potential building blocks for the design and development of optoelectronic devices such as organic light-emitting diodes (OLEDs) and solar cells. These heterocycles also exhibit promising applications in nonlinear optics as well as in various chemical transformations such as oxidation, reduction, and coupling reactions. They can also function as fluorescent probes for the detection of heavy metal ions, pH, and biological molecules, and as photocatalysts. In this study, we characterized the photophysical properties of derivatives of 2,1,3-benzoxadiazole, in which the structure of the central nucleus promotes the formation of highly organized molecular arrangements characteristic of liquid crystals. Specifically, the photophysical properties of 2,1,3-benzoxadiazole compounds with different symmetric branches, 4b ($C_7H_{16}0$) and 4e ($C_{12}H_{25}NO_3$), were studied in solvents with different polarities and in film form. The absorbance of both compounds occurs in the visible region, with a peak at 413-420 nm for 4e and slightly higher at 430-442 nm for 4b. The fluorescence quantum yield varied from 0.3 to 0.8, depending on the solvent, and the Stokes shift ranged from 2300 to 4500 cm-1 for both solvents. The excited state lifetimes were approximately 2.0 ns. The photophysical properties of the films were similar to those of the solution samples in terms of maximum absorption and the shape of the absorption and fluorescence spectra. However, the Stokes shift of the films was higher. The values of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) were estimated for compounds 4b and 4e. The estimated values for HOMO and LUMO were -5.00 eV and -2.23 eV, respectively, for compound 4b, and -5.01 eV and -2.06 eV, respectively, for compound 4e. The estimated values for HOMO and LUMO suggest that these compounds are promising candidates for use in OLEDs, organic solar cells, and

Polarization-resolved Z-scan technique to discriminate the nonlinear refractive index of optical glasses

Renato Mafra Moysés[1], Emerson Cristiano Barbano[2], Lino Misoguti[1]

[1]Instituto de Física de São Carlos - USP (*Photonics Group*) , [2]Universidade Federal do Paraná (*Physics Department*)

e-mail: renatomaframoyses@usp.br

Synthesis of new optical glasses with high nonlinear refractive index plays an important role in optics and photonics, especially for all-optical switch applications. However, depending on laser pulse width, wavelength, and repetition rate, different nonlinear refractive effects can arise simultaneously. Indeed, there are three main nonlinear effects that can emerge in materials: nonresonant electronic, molecular orientational and thermal, which need to be discriminated. For example, pump and probe techniques can be employed [1] to discriminate these effects based on their response times, but they require complex two or more beam setup. On the other hand, we can use a single-beam method: the polarization-resolved Z-scan (PRZS) [2], to discriminate them. Our technique explores the laser polarization (linear and circular) and repetition rate to do so. This was possible thanks to newly available femtosecond pulses systems which repetition rate can be controlled from very high to low where thermal effect takes place or not, respectively, such as the Carbide laser from Light Conversion (515 nm, ~200 fs, with controllable pulse repetition rate:1-1000 kHz). Here, we propose using PRZS to characterize optical glasses. To validate our methodology, we conducted measurements on three significant glasses: SF6, LaSF-N30, and a neutral density filter. Our findings revealed the presence of pure electronic and thermal effects, while no orientational contribution was observed.

Clean energy has become a topic of ever increasing interest in recent times. An effective method of producing clean energy is through Organic solar cells (OSCs)[1]. A crucial mechanism in this device is the donor-acceptor (D-A) heterojunction, where photoinduced charge separation occurs (electrons and holes). Commonly, Indium Tin Oxide (ITO) is used as anode due to its high work function (4.62-4.81 eV)[2] and a metal with low work functionis used as anode. However, these low work function metals are easily oxidized, making theOSCs less durable in ambient conditions. By preparing inverted cells, this problem is circumvented. In this cells, ITOs work function is lowered by chemical modification and so it can play the role of cathode and a high work function metal can work as anode. It has been noted that by doping its surface with cesium carbonate ($Cs2CO3$) its work function is lowered to about 2.5 eV [3]. However, it is not clear how reproducible is the relation between chemical modification and work function lowering and the mechanism of such effect. In this work we prepared and characterized pellets of $Cs2CO3$ doped ITO nanoparticles by ball milling and thermal annealing. We determine the distribution and quantify the $Cs2CO3$ on the ITO using Energy dispersive spectroscopy (EDS). Atomic Force Microscope is used to analyse the topology of the pellets. X-ray photoelectron spectroscopy (XPS) is used to measure the work function of the materials.

Preparation and characterization of phenothiazine oligomers as low bandgap organic system

Bruno Silva Simão[1], Bruna Castanheira[1], Thiago Queiroz[1]

[1]Universidade Federal do ABC (*Centro de Ciências Naturais e Humanas*)

e-mail: bruno.simao@aluno.ufabc.edu.br

Donor-acceptor molecular systems for organic photovoltaics (OPVs) are composed by an association of an low-bandgap oligomer with an electron defficient acceptor.[1] Thus, the design and preparation of low-bandgap oligomers with high absorbance in the solar spectrum and high hole conductivity is an important step towards efficient OPVs. We hereby propose an association of oligophenothiazines that can be formed of benzoid and quinoid structures to prepare such low-bandgap oligomers. The benzoid units are electron donors while the quinoid are acceptors, thus, benzoid-quinoid association is a smart strategy to prepare intramolecular "pull-push" electron conjugations that favors the bandgap lowering. However, it is not clear how the molecular size and the ratio between quinoid and benzoid structures inpact the bandgap of the oligomer, neither it is well established chemical routes to obtain oligomers with controlled molecular structure. In a first approach, we carried out an interfacial oxidative polymerization (IOP) of the monomer using ammonium persulfate (APS) as the oxidizing agent in a toluene-isopropanol mixture[2]. We also prepared oligomers by the IOP method and APS oxidizer using glacial acetic acid solvent and higher temperature[3]. The quinoid/benzoid ratios and cross linking characteristics were determined by liquid-state nuclear magnetic resonance (NMR) spectroscopy. In addition, we report the optical characterization from UV-VIS absorption and the optical gap of the oligomers.

Preparation of stable luminescent films containing chitosan and neutral conjugated polymer as a compatible matrix for small molecules

Alessandra Stacchini Menandro[1], Cornelia Bohne[2], Laura Oliveira Péres[3] [1]Federal University of Sao Paulo, [2]University of Victoria British Columbia (***Department of Chemistry and Centre for Advanced Materials and Related Technologies***) , [3]Federal University of Sao Paulo (***Departamento de Química***)

e-mail: alessandra.menandro@gmail.com

Conjugated polymers embedded in biopolymer films are promising materials due to their luminescent properties and the possibility to apply in photoresponsive devices [1]. Chitosan is a biocompatible material with the ability to form self-standing and malleable films [2]. Even though chitosan was shown to be miscible and compatible with other biopolymers andionic polymers, the incorporation of insoluble neutral conjugated polymers and small molecules could be challenging. The objective of this work is to understand how a conjugated polymer, poly(3-hexylthiophene-co-1,4-phenylene) (PTPh), can be incorporated into a self-supporting film containing chitosan and how this new film can enhance thedispersion of small molecules. The 4-aminoazobenzene (4-AAB) was chosen as a small molecule since its cis-trans photoisomerization provides information on the localenvironment in the microheterogeneous film. Using spectroscopy and microscopy it was observed the complete phase separation of 4-AAB into chitosan films. However, in presenceof PTPh, compatible and stable films were obtained. PTPh luminescence showed to changein presence of 4-AAB. Thus, the luminescent properties of PTPh when effectively dispersedin a chitosan matrix can be used to gain information on the reasons for the much betterdispersion of 4-AAB into the chitosan matrix. These results are a consequence of the molecular interactions between all components in the film. Hence, this work provides fundamental and methodological approaches to incorporating small molecules into stable, self-standing, and luminescent polymeric films for potential applications in fluorescencemodulation, sensors, and optoelectronic devices.

e-mail: marleaneaz@gmail.com

The morphological characteristics and alterations of the active layers and electrodes due to the degradation of the resistive memories after several write/read/erase/read cycles need to be analyzed. In this work, we focus on the degradation of a memory device formed by poly (2-methoxy-5-(2''ethylhexyloxy)-1,4-phenylene vinylene) (MEH-PPV) as an active layer sandwiched between two electrodes, Indium Tin Oxide (ITO) and Aluminum (Al). It was observed that the aluminum electrode after more than 100 cycles began to show regions with defects. The Raman and Scanning Electron Microscopy (SEM) techniques together with EDS were used to understand the structural and conformational changes due to device degradation. The SEM image of the aluminum electrode showed regions of permanent degradation (holes). The EDS analysis shows that in this region there are remnants of materials that formed the device: In the center ITO signal, and in the border region mix signals of aluminum, polymer, and ITO. All layers are altered, including the ITO electrode. The Confocal Raman microscopy shows different characteristic signals: MEH-PPV in the border of the hole, ITO, and glass in the center. Similarly, Li et. al. [2] analyzed the MEH-PPV/aluminum interface obtaining practically the same features. Thus, in our case, spectral characteristics indicate weak MEH-PPV/Al interfacial interaction, therefore the formation ofa native aluminum oxide layer at the interface may be considered since Al has a strong affinity with oxygen. It is possible that the degradation of the device is the result of several processes such as a strong discharge process and the production of O2 gas when voltage was applied repeatedly to make the read-write-read-erase cycles.

The high demand for new materials with enhanced optical features has led to a growing interest in molecular nonlinear optics. This area of research has facilitate the creation of more efficient materials and a decrease in the cost of recent technologies. In particular, the macromolecules has received a special attention due your high symmetry breaking being a excellent candidate for presents a great values of second order optical susceptibility [1] $\chi 2$. The polybinaphthalenes has a ideal macromolecular structure to link differents chromophores to optimize the nonlinear optical responses [2]. In this context, we determined the spectral dependence of the first order molecular hyperpolarizability $\beta(\lambda)$ of four donor-embedded polybinaphthalenes (DEP) structures in solution. For this, we apply the tunable femtosecond Hyper Rayleigh Scattering (HRS) technique [3]. The results showhigh β values for all studied macromolecules, with peak values ranging from 2500 to 16000 ($x10^{-30}$ cm^4 $statV^{-1}$). Concerning the values of β for pNA molecule, the (DEP) are c.a. 25 to 160times higher at the enhancement resonance region. This giant molecular second harmonic generation makes these class of macromolecules an exceptional candidates for photonic devices, such as, in the fabrication of highly efficient organic crystals for second harmonic generation.

e-mail: alicefilipak@alunos.utfpr.edu.br

The design of lanthanide complexes has been an important research goal owing to their applications such as lighting sources and sensors. This study describes the synthesis, characterization, and solvatochromic properties of a Eu^{3+} complex, using cheaper ligands as antennas when compared to usual ones, obtained as follows: $Eu(NO_3)_{3(aq)}$ was added to a solution of 3,5-Dihydroxybenzoic acid, Hdic, and 2-hydroxy-4-methoxy-benzophenone, Hbzf, (ratio 1:2) in DMF, and the precipitate was isolated after filtration and washing with a mixture of water/DMF. FTIR showed the coordination of Eu^{3+} via carbonyl group due to the shift of 42 cm^{-1} in the ν_{as}(C=O) stretching, and Eu^{3+} titration, as well as CHN analysis results, allowed the proposition of the stochiometric formula $[Eu(dic)_2(bzf)(DMF)(H_2O)]$. The produced complex exhibits the characteristics *f-f* Eu^{3+} transitions [1] and τ = 0.20 ms. The T_1 was calculated via an isostructural Gd^{3+} complex (19.710 cm^{-1}), suggesting that the ligands act as a suitable antenna for Eu^{3+}. In addition, a solvatochromic study was performed using several solvents with different polarities to explore the spectroscopic properties of the complex. The solvent sensitivity to the complex was evaluated by the Lippert-Mataga plot, where the polarity function exhibits a good correlation with pseudo-Stoke's shift (R^2 = 0.94), when compared to the literature [2]. Finally, the observed correlation suggests that the solvatochromic shift can be explained by a dielectric solute-solvent interaction. In conclusion, the desired complex was successfully synthed and has promising optical features in sensing based on its solvatochromic properties.

e-mail: r.silva@ufma.br

Physical properties of organic salts can change under extreme thermodynamics conditions [1-2]. Here, we investigated the vibrational and structural properties of glycinium maleate crystal (GM) via High-Temperature Raman Spectroscopy (HTRS) and High-Temperature Powder X-ray diffraction (HTPXRD). GM was obtained in 38 days by slow evaporation method from solutions of glycine and maleic acid (Sigma Aldrich, 99%) at 1:1 ratio. HTPXRD were performed on Empyrean powder diffractometer of Panalytical (Cu Kα radiation, λ = 1,5418 Å); with 0.02° and 2s/ste 2θ range 5-50°. GM was studied by Thermogravimetricand Differential Thermal Analysis (TG-DTA) using a DTG-60 instrument (Shimadzu) - Al crucible, N2 atmosphere (flux of 100 mL/min.), heating rate of 5 K/min. HTRS, from 298 to 438 K, was performed on TriVista spectrometer (Princeton Instruments) and He-Ne laser (λ = 632.8 nm). HTPXRD suggested conformational modifications in the range of 403-423 K, owing to intensity inversion of peaks at 24,04° and 26,88°. TG-DTA curves indicated good thermal stability up to 397 K and temperatures of melting process, thermal decomposition, and glycine liberation at 415, 438 e 499 K. Agreeing with that, HTRS reveal spectral changes around 408 K due to modifications in bands associated with glycine atomic groups, followed by a phase transformation caused likely by glycine liberation.

Study of a perylene diimide derivative liquid crystal for organic solar cells applications

Carlos Henrique Stadtlober[1], Harald Bock[2], Juliana Eccher[1]

[1]Universidade Federal de Santa Catarina (*Departamento de Física*) , [2]Centre de Recherche Paul-Pascal

e-mail: carlosstadt@gmail.com

Organic solar cells (OSCs) are an interesting option for reducing environmental impact. The main benefit is the ability to produce lightweight, flexible and portable devices that can be used in daily life. In this field, the search for non-fullerene acceptor materials (NFAs) is currently one of the main focuses. Columnar liquid crystals (ColLCs) based on perylene diimide are among the promising materials to replace fullerenes. ColLCs have the advantage that molecular alignment can be controlled to obtain charge transport in the desired direction [1]. By combining their excellent optical, self-assembly and semiconducting properties, ColLCs became very attractive for applications in OSCs. In this work, the polymer PFO-DBT was used as the donor (D), and a room-temperature ColLC based on a benzoperylene diimide diester as the electron acceptor (A). The absorptionspectra of the two materials are complementary, covering a range from 300 to 650 nm. Inthe presence of the polymer, the photoluminescence (PL) of the ColLC is quenched. This quenching can be caused by a D:A charge transfer or even by an energy transfer between the materials. Thin films of the mixtures were aligned with the ColLC molecules in face-on orientation. Higher absorption and PL intensities were obtained from aligned samples. AFM measurements revealed homogeneous surfaces with a reduction in the roughness values for the mixture films. Also, different amounts of the solvent additive DIO were added to the polymer:ColLC films. The crystallinity of the films increased by increasing DIO concentration, indicating an improved morphology. Finally, electrical measurements were carried out to obtain the performance of the ColLC as an acceptor material and also as the electron transport layer.

e-mail: ukrainski.rafaela@unifesp.br

Corrosion is a common phenomenon in reinforced concrete structures. This phenomenon, however, results in a significant loss of resistance to tensile stresses in structures, making them more fragile and inefficient for various applications[1]. In order to avoid and/or reduce this pathological manifestation, the use of composite materials involving conjugated polymers and metallic nanoparticles for protecting reinforced concrete structures has been studied[2]. Thus, this work studied the formation of a composite for covering CA-50 steel reinforcements, containing epoxy (commercial anticorrosive paint), poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) polymer, very popular and with good corrosion inhibition characteristics[3], and copper nanoparticles (CuNPs) which can aid in adhesion to the substrate and protect against microbial corrosion. Finally, the corrosion parameters from the CA50 steel were analyzed using the potentiodynamic polarization technique. For this, four solutions that simulated pore waters existing inside the reinforced concrete were used, namely: AP1 Ca(OH)2 sat. + 0,004% NaOH + 0,1% KOH; AP2 Ca(OH)2 sat. + 0,004% NaOH + 0,1% KOH + 1,0% NaCl; AP3 0,20% NaOH + 0,20% KOH e AP4 0,004% NaOH + 0,1% KOH + 1,0% NaCl. Through the aforementioned test, it was observed that AP4 was the most aggressive pore water for this steel. Scanning electron microscopy (SEM) of the steel without the coating showed the formation of pores after carrying out the linear polarization with the AP4 solution, and showed that the resulting corrosion product was essentially iron oxide.

Study of energy transfer in self-assembled structures of dipeptides containing carbazole derivatives via Fluorescence Lifetime Imaging Microscopy.

Diéricon Sousa Cordeiro[1], Tatiana Duque Martins Ertner de Almeida[1]

[1]Universidade Federal de Goiás (*IQ*)

e-mail: diericonquimicaufg@gmail.com

The first publications of self-organizing structures of organic molecules appeared in 1976[1]. However, only in 1993, Ghadiri et al, published a work about the synthesis and characterization of peptide nanotubes (PNT)[2]. In addition to nanotubes, peptides are reported in the literature to organize themselves in various structures such as nanovesicles nanowires, hydrogels, nanofibers, and others[3-4]. Studies indicate that the interactions that control the formation of these self-organizing structures may become more dominant as the solvent and concentration solution varies, and consequently the effects on the self-organization of the structures. In this work self-organizing structures of two dipeptites: Phe-Phe and Tyr-Phe, were produced using polar and nonpolar solvents: deionized water, methanol and tetrahydrofuran and adding carbazole derivatives in the samples. The formed structures have fluorescence emission in the blue and green region. Fluorescence lifetime imaging microscopy (FLIM) was used to image the structures formed in order to obtain the fluorescence lifetime parameters of the structures for the dynamic study of the energy transfer processes that occur in these systems. It was observed that the dynamics of the processes change significantly between the structures formed and between the dipeptides used. These processes establish information of extreme importance for the application of these systems in optical sensors, photoluminescent devices and the active layer of photovoltaic systems.

In recent years, many research groups have carried out theoretical and experimental investigations on nonlinear optical (NLO) organic chromophores [1] for applications in electronics and photonics [2]. In this work we performed the computational modeling of 15 chromophores, with 14 of them having novel structures and studied their electronic properties. Among these, we synthed and characterized 10 chromophores containing the heterocyclic 1,3,4-oxadiazole as the core of the molecule structure. The center of the structure was attached on one side to phenylene and alkyl end groups, and on the other side to thiophene or pyridine groups. We analyzed the effects of varying the terminal group and the aromatic bridge (oxadiazole + phenylene group) on the nonlinear optical properties (NLO) of chromophores. We found that variation in the terminal group has a greater influence on the NLO properties than a change in the central part of the molecule [3]. We investigated the photophysical and nonlinear optical properties by studying luminescence and hyper Rayleigh scattering (HRS) respectively. The computational study of the nonlinear optical properties was performed through density functional theory (DFT-TD) using the B3LYP functional and the 6-31+G(d,p) basis set. The compounds showed high values of hyperpolarizabilities, indicating that they can be applied in optoelectronic devices.

Abstract: Organic molecules have been the target of several studies for developing applications in Optics and Photonics [1]. Specifically, these molecules are widely used in the nonlinear optical regime, when the intensity of the excitation light is comparable with the interatomic electromagnetic field. Some nonlinear processes, such as microfabrication, excited fluorescence microscopy and optical storage, allow technological advancement in several areas. In this project, we aim to study the nonlinear effects of the pure commercial perylene, a conjugated organic molecule, specifically the absorption of two photons, in three different solutions, they being the toluol, the dichloromethane and the chloroform. Perylene and its derivatives are already used in applications, such as in optoelectronic devices, in dye lasers and gas sensors, due to their high fluorescence. Among the available techniques to study optical nonlinearities, the Z-Scan[2] stands out. This technique consists, in general terms, of varying the position of the sample along the beam focusing axis, analyzing the normalized transmittance. In addition, measurements of linear parameters, such as molar absorptivity, fluorescence quantum efficiency, fluorescence lifetime, anisotropy coefficient and dipole moment difference between ground state and excited state, determined by linear spectroscopic techniques, were performed. We observed interesting linear optical processes, as well as high two-photon absorption cross-section for perylene, prompting this compound for application in Photonics.

Copper(II) (Cu(II)) has the ability to accept electrons from ligands, resulting in charge transfer and complex formation [1]. Therefore, these study aimed to synthesize and characterize crystals of glycine complexed with Cu(II) through slow solvent evaporation. A 2:1 molar ratio solution of glycine and $CuSO_4.5H_2O$ in deionized water, was stirred for 2 hours at room temperature (~299 K), and then adjusted to pH 7.0 with NaOH. The solution was left at rest on a bench at a temperature of ~299 K for crystal growth. The material was characterized by refined XRD using the Rietveld method, FTIR, TGA-DTA, and DSC. Blue needle-like crystals were obtained in 7 days, crystallizing in an orthorhombic system with space group P212121 with four asymmetric units per unit cell (Z = 4), consistent with literature data [2]. Bands identified in the FTIR spectrum showed C–N bonds in the range of 1250 to 1020 cm^{-1}, and characteristic bands of NH^{3+}, C = 0, CH_2 groups. Through TGA-DTA and DSC, endothermic events, dehydration, and fusion were observed. From the results, glycine acted as a bidentate ligand and formed a complex with Cu(II), with potential in biological and optical applications.

Transparent Conductive Electrodes (TCEs) have been widely studied due to the growing need to produce new Organic Devices. One of the most widely used TCEs is Indium Tin Oxide (ITO - Sn:In_2O_3), which is mainly used as a transparent conductive thin film in electronic devices. However, ITO is rigid, brittle, and has high commercial costs, which makes it unsuitable for flexible electronic devices. Due to these limitations, several carbon and metallic nanomaterials have been used for the development of electrodes with high transparency and conductivity, including Graphene Oxide (GO) and Silver Nanowires (AgNWs). In this work, the synthesis and characterization of Silver Nanowires and reduced Hydroxyl-rich Graphene Oxide (rHGO) were carried out aiming to be used as efficient TCEs for Flexible Organic Devices. The synthesis of AgNWs was performed using a modified polyol method [1], while the synthesis of rHGO was prepared using a chemical route based on the modified Hummers method [2]. These two nanomaterials were used to produce and optimize hybrid films of rHGO and AgNWs, which combine the excellent adhesion and flexibility of GO with the high conductivity and transparency, and the low sheet resistance of AgNWs. Samples of these nanomaterials were analyzed using different spectroscopic techniques and electrical characterizations. Optimized hybrid films showed sheet resistances ranging from 10.3 Ohm/sq to 32.2 Ohm/sq with transmittances between 82.6% and 90.1%. These results show that our TCEs are comparable to the ITO films, which have sheet resistance between 10 Ohm/sq and 30 Ohm/sq and transmittance above 90%, with the advantage of being suitable for flexible organic electronics applications.

e-mail: jchacaliaza@usp.br

Germane-tellurite glasses doped with Er^{3+} were fabricated by conventional melt-quenching method with the chemical composition: (60-x)% TeO_2- 20% ZnO - 10% GeO_2- 10% Na_2O - x% Er_2O_3, where x represents the changes in the %mol concentration of Er_2O_3 in the samples: (x = 0.00, 0.001, 0.01, 0.05 and 0.1). The structural properties were studied by X-ray diffraction, Raman and FTIR [1]. The spectroscopic properties in the visible and near-infrared regions are studied by means UV-Vis-NIR absorption, refractive index, lifetime, emission, excitation, and photoluminescence measurements and afterward, the influence of Er^{3+} doping on the vitreous structure was studied, analyzing the optical bandgaps, Urbach energies, Judd-Ofelt parameters, and boson peaks [1]. The optical properties of the glasses indicate good transparency in the visible region, as well as a dependence between the content of Er^{3+} doping and the hypersensitive band of Er^{3+} ($^2H_{11/2}\rightarrow{}^4I_{15/2}$) and also the energy transfer mechanisms in the up-conversion process of glasses are described [2]. These results provide a complete explanation of the dynamics of Er^{3+} ions within germane-tellurite glasses for laser and photonic applications [3].

Systematic Characterization of Cumarin 6 in Different Solvents and Concentrations for Photophysical Analysis and Technological Applications

Bruna Bueno Postacchini[1], TAYLAINE APARECIDA PERUCCI[1], Thiago Cazati[2]

[1]Universidade Federal de Ouro Preto (*DEFIS*) , [2]Universidade Federal de Ouro Preto (*Departamento de Física*)

e-mail: bruna@ufop.edu.br

Coumarin 6 has been used as a spectroscopic standard due to its high quantum efficiency of singlet state formation. In this study, a systematic characterization of Coumarin 6 was performed in different solvents and concentrations by calculating the fluorescence quantum efficiency using the comparative method and the excited state lifetimes. The use of Coumarin 6 as a spectroscopic standard was found to be suitable at concentrations between 0.735x10^{-06} and 2.20x10 $^{-06}$mol/L, as there were no changes in the shape of the optical absorption and fluorescence spectra. Within this concentration range, there was no significant variation in the efficiency or lifetime of the excited state. At the concentrations used, the polarity of the solvent was found to be the most important factor, as the Stokes shift as a function of solvent polarity (Lippert-Mataga diagram) exhibited a linear behavior even for protic solvents. There was no formation of aggregates or hydrogen bonds at the concentrations and solvents used. In different solvents, higher quantum efficiency of fluorescence was observed for more polar solvents. The excited state lifetimes of Coumarin6 were found to be around 2.3 to 2.6 ns for different solvents, with nonradiative constants being predominant in methanol and acetonitrile, and radiative constants being predominant in chloroform and dichloromethane. Knowledge of the photophysical parameters of reference standards is extremely important for calculating the photophysical properties of new compounds. In addition, controlling the photophysical processes of any chromophore promotes the design of technological applications for organic chromophores. Chromophores such as Coumarin 6 also have applications as fluorescent probes for investigating the polarity of the environment, the efficiency of chemical reactions, tracking of nanodrugs, fabrication of active layers of solar cells, and many other photonic processes.

Systematic study of the $Cu_{2-x}Se$ electrode and it'sinfluence on charge transport mechanisms

Bruno Souza Zanatta[1], Silésia de Fátima Curcino da Silva[1], Pedro Henrique Dondori Zaramella[1], Otávio L. Bottecchia[2], José de los Santos Guerra[1], Erick Piovesan[1], Alexandre Marletta[1]

e-mail: brunosouzanatta@gmail.com

The field of organic semiconductor electronic devices has created a need to find new materials, due to it's advancement, to replace the traditional indium-doped tin oxide (ITO) and fluorine-doped tin oxide (FTO) electrodes. This work was a continuation of the research developed by Silva et al.[1]. Here, a study was made of the change in the thickness of the $Cu_{2-x}Se$ electrode during it's chemical production process. The $Cu_{2-x}Se$ electrode was selected due to it's electrical, optical and mechanical properties presented in the literature. The OLED is made with aluminum as the cathode, poly[2-metoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) as the active layer, poly(3,4- ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) as an organic layer for hole transport and $Cu_{2-x}Se$ as an anode. Through the analysis of the obtained data and empirical investigations on the film conversion process, it was possible to discover an ideal time for the chemical bath of the electrode. Within 30 seconds of chemical bath to obtain the $Cu_{2-x}Se$ electrode, the OLEDs had charge injection only by the direct tunneling effect. Thus, it was shown that it is possible, through a chemical process, to change the $Cu_{2-x}Se$ electrode transport mechanism. To complete this work, EIS study was conducted to confirm the results obtained previusly.

e-mail: ritadecassia.fisica@gmail.com

This work aims to explore and to explain the photophysical behaviours in a series of pure organic molecules, which can exhibit room temperature phosphorescence (RTP) and high efficiency photoluminescence, by changing the moiety geometry position. These two interesting effects were observed in different molecules, room-temperature phosphorescence in air atmosphere and a high photoluminescence quantum yield (PLQY >70%), both properties are widely desirable, being RTP used as moieties for donor-acceptor molecules, bioimaging, and a high PLQY as a hyperfluorescence in active layer for devices. Experimental procedures were performed in order to fully determine the molecular photoluminescent properties, such as environmental effects, singlet-triplet alignment and S-T energy levels, charge transfer states, photoluminescence temperature dependence and photoluminescence lifetimes.

The Influence of Wetting on the Impedance Modulus of PVC/CNT Electrospun Membranes

Sérgio Henrique Pezzin[1], Marcio Briesemeister[2], John A Gomez-Sanchez[3], Pedro Bertemes Filho[4]

[1]Fundação Universidade do Estado de Santa Catarina (*Química*) , [2]Fundação Universidade do Estado de Santa Catarina (*Pós-Graduação em Ciências e Engenharia de Materiais*) , [3]Fundação Universidade do Estado de Santa Catarina (*Engenharia Elétrica*) , [4]Fundação Universidade do Estado de Santa Catarina (*Departamento de Engenharia Elétrica*)

e-mail: sergio.pezzin@udesc.br

Membranes of PVC (polyvinylchloride) produced by electrospinning are useful for a variety of applications, such as air and water filtration systems, batteries, and protective clothing [1,2]. Among the characteristics of electrospun PVC membranes, it can be highlighted the mechanical resistance, the adjustable hydrophobicity, and the high porosity [1]. The combination of PVC with functional nanofillers, such as CNT (carbon nanotubes), might be used to further expand the use of the material [2]. The present study aims to evaluate the influence of wetting on the electrical impedance spectra for electrospun PVC/CNT membranes. PVC electrospun membranes containing up to 3 wt% CNT were prepared from THF/DMF solutions (18 wt% PVC, 20 kV, 15 cm NCD). They were characterized by FE-SEM and TEM in order to both analyze the fiber morphology and verify the dispersion of CNT inside the nanofibers. Finally, electrical impedance spectroscopy measurements were obtained for both dry and wet mats in the frequency range of 100 Hz to 1 MHz. No significant differences between impedance spectra and CNT concentration were found for dry membranes. On the other hand, a reduction in the impedance modulus from 8.1% (neat PVC) to 99.8% (3 wt% CNT) was observed for wet membranes. The last showed an exponential decrease of the impedance modulus with increasing the CNT concentration. This behavior might be related to the presence of carboxylic groups on the CNT surface, which enable proton conduction under wet conditions. TEM images show that most of the nanotubes are oriented along the fiber direction, while SEM micrographs evidenced membranes with homogeneous fiber distribution.

e-mail: vitoriavasconcelos@alu.ufc.br

Chalcones can present nonlinear activity: a substantial electron donor, a highly polarizable π-conjugated bridge, and a π-electron acceptor. Furthermore, a chalcone molecule with a π-conjugated system provides a significant charge-transfer axis with appropriate substituent groups on the terminal aromatic rings. Therefore, compared to conventional chalcones, bis-chalcones have a more extensive conjugate system, which results in a more significant overlap of molecular π orbitals, making them suitable for applications in optoelectronic devices. In this context, some parameters are essential, such as the electronic gap (E_g), the Highest Occupied Molecular Orbital (HOMO), and the Lowest Unoccupied Molecular Orbital (LUMO). Thus, the effects of increasing π-conjugation on decreasing theoretical and experimental gap energy for chalcones (1E,4E)-1,5-diphenylpenta-1,4-dien-3-one (DBA) and (1E,3E,6E,8E)-1,9-diphenylnona-1,3,6,8-tetraen-5-one (DBCN) synthed by the Claisen-Schmidt condensation method were investigated. Initially, conformers with minimum energy were geometry optimized through the Density Functional Theory (DFT) using the exchange-correlation functional M06-2X and 6-311+G(d,p) basis set. Then, we computed the vertical excitation energies and oscillator strengths to simulate the electronic absorption spectra (UV-Vis) keeping the same functional and basis set of the geometry optimization step. Finally, the Tauc graph was generated to compare the measurement of solid samples in diffuse reflectance performed in Shimadzu UV-2600 spectrophotometer using an integrating sphere ISR-2600Plus with $BaSO_4$ calibration standard.

e-mail: sergiocurcio@hotmail.com

Difluoroboron β-diketonates complexes are highly luminescent with extensive properties such as their fluorescence both in solution and in solid state and their high molar extinction coefficients. Due to their rich optical properties, these compounds have been studied for their applications in organic electronics such as in self-assembly and applications in biosensors, bio-imaging and optoelectronic devices. The present work aims to study the photophysical and electrochemical properties of novel fluorescent difluoroboron flavanone β-diketonate complexes in different solvents and solid thin films [1]. The photophysical studies revealed that the substituent groups and the solvent media significantly influencethe electrochemical and photophysical properties of the final compounds, especially the molar absorption coefficient, fluorescence quantum yields, and the band gap. Moreover, thecompounds exhibited a single excited-state lifetime in all studied solvents. In solid films, theabsorption bands of the compounds showed a red shift when compared to absorption spectra in solution and the excited state decays of the films showed reduced lifetime, suggesting J-type aggregation of molecules. Electronic structure calculations using DensityFunctional Theory (DFT) and Time-dependent density functional theory (TDDFT) were performed to assess ground and excited state properties of the compounds and determinetheir theoretical absorption spectra.

Two-photon absorption and dynamics of excited statesin Bromo-Chalcone derivatives

Nathan Barbola Marucci[1], João Victor Pereira Valverde[1], Cleber Renato Mendonca[1]

[1]Instituto de Física de São Carlos - USP (*FCM*)

e-mail: nathanbarbola@usp.br

Chalcones are a family of organic compounds that exhibit good nonlinear optical properties [1]. Additionally, they have a relatively simple synthesis and various pharmacological properties, making them promising subjects of study, with potential applications in areas such as bio-photonics. In this work we study the dynamics of excited states and the effect of substituents (electron donors and acceptors) on the two-photon absorption (2PA) cross-section of bromo-chalcone derivatives using the z-scan technique [2]. Nonlinear optical experiments are performed using 200-fs pulses from a YGW laser system, which, when coupled with an optical parametric amplifier, allows for tuning the excitation wavelength from the UV to the near-infrared. Therefore, the 2PA cross-section spectrum is obtained, enabling to correlate the nonlinear optical response with the molecular structure. Initially we have selected a few chalcone compounds, which were diluted in DMSO, and their linear absorption and fluorescence spectra have been measured. It was observed that the samples exhibited two UV absorption bands, except for the one with the amino group (-NH2), which showed a significant shift of the first band (now centered at 432 nm). Such a molecule was also the only one that exhibited fluorescence, centered at 558 nm. Yet, from the open aperture (absorptive) z-scan measurements with this sample, it was observed that the transitions allowed by one photon were also allowed by two photons, which is a characteristic of a non-centrosymmetric molecule. Further studies are being performed with the other chalcone compounds to correlate the nonlinear spectrum and specific molecular features.

e-mail: joaovalverde@ifsc.usp.br

In recent years, the search for novel organic materials capable of absorbing two photons has grown due to their potential applications in three-dimensional optical data storage, microfabrication, high-resolution three-dimensional imaging of biological systems, optical power limitation, and photodynamic therapy [1]. In addition, the two-photon absorption (2PA) process is an important tool for understanding the relationship between electronic/molecular structure and optical properties at the molecular level [2]. Among various organic compounds, diketopyrrolopyrrole derivatives, also known as DPPs, have shown remarkable properties, such as an accessible synthesis route, easy modification by incorporating substituents, high fluorescence quantum yield, and planarity. Such features makes DPPs an extremely interesting structure. However, there is little information about the nonlinear optical properties of DPPs. Here, a complete characterization of two symmetric dithienyl-diketopyrrolopyrrole derivatives was carried out, exploring the influence of the thienyl moiety (an electron-rich structure acting as an extension of the π-conjugation) and the bromine atom in the 2PA process. The results were quite promising, with both compounds exhibiting a 2PA band in a dark 1PA spectral region, as expected due to the dipole selection rule. The substitution of hydrogen atoms with bromine led to 1.4 times increase in the 2PA cross-section value. This effect was associated with a greater electronic delocalization observed in the structure containing the bromine atom. This showsa possible path towards the architecture of molecules with larger nonlinear linear responses.

Unraveling the ICT character in D-A copolymers: an experimental and theoretical approach.

Harison Jean de Toledo[1], Lucas Scalon[2], Luis Octavio Araujo[3], Cleber F. N. Marchiori[4], Paula Cristina Rodrigues[1]

[1]Universidade Tecnológica Federal do Paraná (*Chemistry*) , [2]Universidade Estadual de Campinas (*Institute of Chemistry*) , [3]Universidade Federal do Paraná (*Chemistry*) , [4]University of Karlstad / Karlstads Universitet

e-mail: harison@alunos.utfpr.edu.br

The donor–acceptor (D–A) approach in the conjugated polymer is an effective method to control the energy levels of the material. For D–A copolymers, the first photoexcitation is expected to correspond to a state where the excited electron is promoted to the first unoccupied orbital, which is mainly localized at the acceptor moiety, while the hole is localized at the donor unit. This characteristic is usually named as internal charge transfer (ICT), an intrachain electron transfer from the electron-rich to the electron-deficient unit. In this work, D–A copolymers composed of diketopyrrolopyrrole (DPP), thiophene (Th), benzothiadiazole (BT), and fluorene (F) as a building block have been synthesized and analyzed in terms of optical properties and theoretical studies. For these, two D-A copolymers, PFBT and PFThDPPTh, were synthesized using Suzuki coupling. The electronic spectra of both copolymers exhibited the dual-band absorption profile (λmax in 317 and 445nm for the PFBT and 370 and 650 nm for PFThDPPTh), suggesting that the ICT processoccurs in both structures. However, our results using density functional theory (DFT) andtime-dependent DFT (TD-DFT) frameworks contrast with what is often observed and reported for other D–A copolymers. For the PFThDPPTh, the theoretical results pointed outthat the HOMO has a major contribution from DDP, while in the LUMO, DPP and Th havesimilar contributions but are still being dominated by DPP. This is in stark contrast withwhat has been reported regarding D–A copolymers. We note that, until now, the designation of a given copolymer as D–A is quite cloudy, based primarily on thevisualization of electronic absorption spectra. In this concern, our results demonstrate that the analysis of the composition of the near gap states is crucial to attribute the character ofa given copolymer, avoiding misinterpretation of the results.

Use of spectroscopy and chemometrics in the study of pen inks applied to Forensic Documentoscopy

Juliani Penha Caland[1], Juliano de Andrade Gomes[2], Jorlandio F. Felix[3]

[1]Universidade de Brasília (*Física*) , [2]Instituto Forense da Polícia Civil do Distrito Federal,
[3]Universidade de Brasília

e-mail: juliani.caland@aluno.unb.br

Use of spectroscopy and chemometrics in the study of pen inks applied to Forensic Documentoscopy
Forensic Sciences have been following the evolution of technical-scientific knowledge and there are currently several areas of specialization in Criminalistics. Among them, we can mention Forensic Documentoscopy, which consists of a set of specialized knowledge aimed at studying and interpreting the material traces of document forgeries and alterations, which may be of interest to the clarification and proof of factual issues, at the service of justice [1]. In this sense, the traces associated with pen inks present in documents collected at a crime scene are object of study of Forensic Documentoscopy, since it allows determining the veracity or otherwise of documents for judicial purposes. Given the need to standardize the operational procedures for document analysis at the Forensic Institutes, Forensic Scientist must develop a protocol for pen ink analysis. In this work, we aimed to combine spectroscopic methods, such as Raman and FTIR, with chemometric methods such as PCA and PLS to allow discriminating manual releases of 62 pen inks of different brands in blue and black colors sold in the national territory in a fast, safe and efficient way. Preliminary results indicated that the combination of spectroscopies UV-VIs and FTIR with PCA enabled the distinction between the types of pen inks available in Brazil in a significant way.

Volumetric capacitance in organic electrochemical transistors: Fundamentals and guidelines on how to correctly measure it experimentally

Marcos Luginieski[1], Gregório Couto Faria[1]

[1]Instituto de Física de São Carlos – USP (*Grupo de Polímeros "Prof. Bernhard Gross"*)

e-mail: mluginieski@gmail.com

Organic electrochemical transistors (OECTs) were first introduced in 1984. However, only in the late 2000s did these devices gain notoriety. In 2015, a big step was taken in understanding OECTs when it was found that capacitance scales with channel volume [1]. In 2016, the so-called volumetric capacitance (C*) was microscopically explained as the product of many parallel plate capacitors between the polymer chain and the solvated ion[2]. Finally, in 2017, C* was established as one of OECT's benchmark. Despite that, the extraction of C* can still be controversial. Usually, it is done by means of electrochemical impedance spectroscopy (EIS). Being a two-terminal technique, the drain and source contacts must be shorted and grounded together. This mimics the OECT operation only when V_D is zero, neglecting any different operation mode or the non-uniform doping profilethroughout the channel. Even so, EIS has been extensively used by the OECT community. The EIS limitation can be overcome by measuring the drain-transient current under a pulsedV_G and analyzing the data in the light of the Faria-Duong model [3]. Being three-terminal based measurements, the drain-transient technique allows one to apply V_D while pulsing V_G. Here, we conducted a thorough comparison between the two techniques, using PEDOT:PSSbased OECT and showing that EIS can be considered for extracting C* only when $V_G >> V_D$. For any other case, only the drain-transient technique provides manners to evaluate the dependency of C* with V_D. By comparing results obtained from both techniques, guidelines for a definitive way of measuring C* in OECTs are discussed and established.

S-Eco-design Strategies of Bio-Polymeric/Nanocellulose Materials: from fundamental aspects to marketing

Bacterial cellulose, fibroin and other biocompatible substrates for organic devices.

Marco Cremona[1]

[1]Pontifícia Universidade Católica do Rio de Janeiro (*Physics*)

e-mail: cremona@fis.puc-rio.br

Recently, great effort has been made to develop both flexible and conformable electronic devices, either as a way to improve ergonomics, making them fit the human body or even to prevent them from breaking under pressure. The search for cheap, sustainable and, mainly, biocompatible materials becomes necessary, since such devices would be subject to long exposure to living tissues. So far, together with the Organic Light Emitting Diodes (OLEDs) and Organic Solar Cells (OSC), there is a demand for new and efficient organic field-effect transistors (OFETs) on biocompatible substrates to allow conformable organic electronics. For the OLEDs great efforts have been reported in the literature to use them in the biomedical field, such as in Photodynamic Therapy. Concurrently, there is a huge interest in the design of advanced materials devised from natural sources. Bacterial nanocellulose (BNC) is a natural polymer synthed by many microorganisms, notably by non-pathogenic strains of ***Komagataeibacter***(***K. xylinus, K. hansenii, K. rhaeticus***). BNC shows distinct physical and mechanical properties make BNC ideal for many areas, including sensors, drug delivery, wound healing, and as conformable/flexible substrates for organic electronics. Other examples of the materials that can be used for this purpose are fibroin, which is a natural biocompatible material extracted from the silkworm cocoon and a new biopolymer obtained from onion pulp (***Allium cepa L.***). BC can be processed with fibroin in order to increase the substrate' s transparency, while cellulose makes fibroin more malleable and robust. Moreover, indium tin oxide (ITO) and SiO_2thin films need to be deposited onto these bio-substrates to obtain conformable, transparent and conductive anodes on top of which organic devices were produced. Here, we review the production methods of these substrates, their properties and applications, focusing on electronic organic devices, especially OLEDs and OFET.

Bacterial celulose. From biomedical to photonics applications

Sidney José Lima Ribeiro[1] [1]Universidade Estadual Paulista / Instituto de Química

e-mail: sidney.jl.ribeiro@unesp.br

Bacterial cellulose or biocellulose (BC) comprises homopolymer of D-glucopyranose residues bonded through β-(1 → 4) glycosidic linkages usually produced by Gluconacetobacter genus. The BC hydrated membranes consist of a three-dimensional network of entangled cellulose nanofibrils, which provides highly porous structures, high surface area, and high purity (lignin- and hemicellulose-free). This cellulose source displays interesting optical, mechanical and chemical properties making it a wonderful material with applications ranging from biomedical (bandages for wounds, burns, templates for bones regenerations and ophtalmological lenses) to photonics (substrates for flexible OLEDs and flexible Random Lasers, photochromic materials, liquid crystalline selfsustainable films, aerogels photocatalysts) [1-3]

All these applications have been touched by our group in the last years and the main results, conclusing remarks and perspectives will be presented.

Acknowledgements: Brazilian agencies, CNPq, CAPES, FAPESP and the National Institute of Photonics are acknowledged for the support.

Bacterial nanocellulose: From fundamental aspects to marketing

Hernane da Silva Barud[1]

[1]UNIVERSIDADE DE ARARAQUARA (*Biotecnologia*)

e-mail: hernane.barud@gmail.com

Bacterial nanocellulose (BC) has received considerable attention in the last years. The unique properties of BC, such as high purity, mechanical stability, thermostability, crystallinity, and biocompatibility make it a promising candidate for commercial applications in different areas (food, electronics, bioengineering, cosmetics and biomedical areas). BNC can be associated with organic/inorganic entities to produce new organic-inorganic nanocomposites (OIN). Using different pathways named bottom-up approach and top-down approach, biopolymer-based OIN can be applied to tailored functionalities and emerging applications. In this lecture I will explore all-BNC products (hydrogels, drug delivery films, food applications, e.g), and I will point out the possibility to increase strength cooperation between academia and industry in the formation of new Start-ups and joint ventures.

Bio-polymer based hybrid materials as functional adsorbents and delivery tools.

Gulaim A Seisenbaeva[1]

[1]Swedish University of Agricultural Sciences (*Molecular Sciences*)

e-mail: gulaim.seisenbaeva@slu.se

Hybrid organic-inorganic materials have broad perspective of application due to combination of functional components. Cellulose is the most abundant bio-polymer that can easily be transferred into nano form. Its surface modification facilitates creation of hybrid materials that can incorporate both organic and inorganic functional components. Cotton-based nano cellulose terminated by carboxylic acid functions possesses strong affinity to metal oxide particles. As nano particles for grafting one can choose either metal oxides strongly binding bio-active molecules/pharmaceuticals for drug delivery, such as TiO_2 [1,2], or oxides possessing important physical (optical or magnetic) characteristics, such as FeO_x [3]. Produced composites display ability to quickly and efficiently uptake several classes of important pharmaceuticals and to deliver them in a chemically or physically controlled way [3,4]. Chemical surface modification with grafting specific ligand functions opens for creation of selective adsorbent materials for recycling of critical metals. Their adsorption and desorption mechanisms have been investigated gaining insights from structural characterization of molecular model compounds [5]. Proposed approaches open prospects for development of circular economy and finding environmental solutions for sustainable future.

Acknowledgments

The authors would like to thank the ÅForsk foundation, grant No. 21-75 and Swedish Council for Internationalization of Higher Education and Research (STINT) grant BR2019-8506 for Brazilian-Swedish collaboration.

e-mail: rr.rosa@fct.unl.pt

Cellulose nanocrystals (CNC) in the form of a stable aqueous suspension, self-assemble intoa liquid crystalline (LC)[1] phase giving rise to solid structures with tunable structural coloration[2]. The chemical versatility of cellulose also leads to a well-known variety of derivatives that can present LC phases. This feature that also impart distinct and interesting properties to the final product but is less exploited in creating new materials. In this small overview, the bio-based polymers on the development of innovative materials are shown. Such as, all-cellulosic composites of CNCs/hydroxypropylcellulose that can create photonic structures that reflect light from UV to NIR wavelength[3]. If microgaps, found within the cross-section of CNCs films, are infiltrated with a nematic liquid crystal, a tunable left- and right-handed CPL system is achieved[4]. Hydroxypropylmethylcellulose in a LC phase displays traveling colored patterns that change the sign of the helix pitch[5] with time. CNCs can also act as matrices for magnetic iron nanoparticles or reinforce chitosan hydrogels for biomedical applications. These examples open new horizons for the application of these renewable materials.

Cellulose nanofibers-based composites for applicationas electronic devices

Daniel Pasquini[1]

[1]Universidade Federal de Uberlândia (*Química*)

e-mail: danielpasquini2013@gmail.com

The use of plant sourced cellulose nanofibers (CNF) to fabricate sustainable and high performance materials is foreseen as a green solution in some areas, for example in the electronic industry and water treatment [1-3]. CNF give adequate H-bonding between the nanofibers resulting in superior mechanical properties, so that composites may be easily produced in the form of resistant and flexible films from the mixture of CNF as a matrix and other components dispersed into it. In this way, we have prepared different composites: i) mixing CNF with conducting polymers polyaniline (PANI) or polypyrrole (PPY), graphene oxide (GO) and magnetic manganese ferrite nanoparticles (MNP) to produce a conducting composite that was tested as electromagnetic shielding; ii) CNF with carbon nanotubes (CNT) in order to investigate their electrochemical properties in view their use in energy storage devices. The effectiveness of electromagnetic shielding in the range of 8.2-12.4 GHz for each of the conductive composites were evaluated and the maximum shielding efficiency at 8.2 GHz in both polypyrrole (-9.14 decibels) and polyaniline (-6.81 decibels) films occurred in films with the highest conductivity values. For the CNF and CNT composites, the cyclic voltammograms obtained for the composites with different percentages of CNT showed a capacitive profile, with the profile obtained for the composite of 50% (m/m) of CNT in relation to CNF, characteristic of supercapacitors with pseudocapacitance. These studies corroborate the versatility of using CNF as a support for new materials with innovative applications.

Cellulose nanomaterials and advanced applications

Alain Dufresne[1]

[1]Institut Polytechnique de Grenoble (*Pagora*)

e-mail: alain.dufresne@pagora.grenoble-inp.fr

There has been an explosion of interest in the use of biomass as a source of renewable energy and materials. This has led to a concurrent increase in the research activity on the biosynthesis, isolation, and properties of cellulose, the key structural component in plant cell walls. One focus of this activity has followed from the recognition that, by suitable chemical and mechanical treatments, it is possible to produce fibrous materials with one ortwo dimensions in the nanometer range from many naturally occurring sources of cellulose. As is usually the case when a new field is developing, the terminology is somewhat confused, but the term "nanocellulose" is now used to cover the range of materials derivedfrom cellulose with at least one dimension in the nanometer range. Nanocellulose-based materials are carbon neutral, sustainable, recyclable, and nontoxic; they thus have the potential to be truly green nanomaterials with many useful and unexpected properties. What is not to love? Multiple mechanical shearing actions can be used to release more or less individually cellulose microfibrils. This material is usually called microfibrillated cellulose. Longitudinal cutting of these microfibrils can be achieved by submitting the biomass to astrong acid hydrolysis treatment, allowing dissolution of amorphous domains. The ensuing nanoparticles occur as rod-like nanocrystals. Similar acidic treatment carried out on starchgranules allows obtaining platelet-like nanoparticles. Impressive mechanical properties andreinforcing capability, abundance, low weight, and biodegradability of these nanoparticlesmake them ideal candidates for the processing of polymer nanocomposites. With a Young' smodulus around 130 GPa and a surface area of several hundred m2.g-1, they have the potential to significantly reinforce polymers at low filler loadings. However, as for any nanoparticle, the main challenge is related to their homogeneous dispersion within a polymeric matrix.

Ecodesign-Inspired Nanocellulose Production: High Efficiency and Customizable Properties with Enzyme-Based Platform Technologies

Valdeir Arantes[1]

[1]Universidade de São Paulo (*Escola de Engenharia de Lorena/Dept Biotecnologia*)

e-mail: valdeir.arantes@usp.br

Enzyme-based technologies can play a significant role in ecodesign for the production of cellulose nanoparticles. This is because ecodesign aims to optimize industrial processes to minimize their environmental impact, while enzyme technologies offer several advantages over traditional chemical and mechanical processes in terms of their environmental friendliness and efficiency. Our efforts have been focused on developing enzyme-based platform technologies that are not only viable, robust, and scalable but also eco-friendly for manufacturing nanocelluloses of different grades suitable for various applications. In this presentation, we will show results to demonstrate that ecodesign-inspired nanocellulose production from hardwood Kraft pulp with enzyme-based platform technologies is an efficient strategy to produce cellulose nanocrystals (CNCs), cellulose nanospheres (CNSs), and cellulose nanofibrils (CNFs) with high yield. It will also cover aspects of how the enzymatic approach can also be designed to tailor the properties (i.e., morphology, surface chemistry, rheological behavior, chemical composition) of cellulose nanoparticles to specific applications.

Electric forces as a tool for manufacturing nanostructured nanocellulose materials: thermoplastic nanocomposites, thermoformable panels and continuous filaments

Antonio José Felix Carvalho[1], Emanoele Maria Santos Chiromito[2], Rafael Grande[2], Eliane Trovatti[3]

[1]Escola de engenharia de São Carlos - Universidade de São Paulo (*Engenharia de Materiais*) , [2]Escola de engenharia de São Carlos - Universidade de São Paulo, [3]UNIVERSIDADE DE ARARAQUARA

e-mail: toni@sc.usp.br

Electrical charges can be useful to produce stable colloidal suspensions due to dominant repulsion forces between particles, as well to produce the opposite effect leading to coagulation and then flocculation of suspensions or to induce order as a driving force to self-assembly. Nanocellulose suspensions can exist as non-charged or charged nanofiber suspensions. Here we discuss the use of such charges to produce very homogeneous nanocellulose composites in non-polar vinyl polymers [1], thermoformable panels of nanocellulose and vinyl polymers [2] and continuous fibers from interfacial complexation of anionic surface charged nanocellulose and cationic natural polyelectrolytes [3]. Thermoplastic nanocomposites and thermoformable panels are produced by the combination of polymer nanoemulsions and nanocellulose suspensions. The final product is produced during coalgulation and flocculation induced by charge neutralization of the polymer emulsion with inorganic coagulants and by the bridging effect induced by nanocellulose which works similarly to non-charged or very low charge high molecular weight polyelectrolyte. The filaments are produced by complexation of a cationic high molecular weight polyelectrolyte such as chitosan and negative charged nanocellulose that again works in a similar manner as a high molecular weight anionic polyelectrolyte.The authors acknowledge to CAPES and CNPq.References:[1] Carvalho, A.J.F.; Trovatti, E.; Casale, C.A., J. Nanocellulose materials for 2D and 3D applications

Gilberto Siqueira[1]

[1]Swiss Federal Laboratories for Materials Science and Technology (*Materials*)

e-mail: gilberto.siqueira@empa.ch

Processing nanocellulose structures with complex architectures and high cellulose contents is chal-lenging. This can sometimes prevent nanocellulose-based synthetic materials from reaching the level of structural complexity and mechanical properties observed in their biological counterparts, such as wood and plant tissues. At Empa, we demonstrate various approaches to manufacture nanocellulose composites, hydrogels and aerogels with high degree of particle alignment and shape fidelity. We prepare soft and stiff composites by our 3D printing methods. Such composites exhibit micro-structures with a high degree of particle alignment and spatially tailored mechanical properties. These materials may find applications in cellulose-based structural, biomedical, soft robots and energy-related products.

Nanostructured Polysaccharides Materials for Water Purification

SABU THOMAS[1]

[1]Mahatma Gandhi University (*Kottayam, Kerala, India*)

e-mail: sabuthomas@mgu.ac.in

The design and synthesis of nano-architected cellulose can act as efficient materials for water purification. The talk aims to study and compare the performance of a polyvinylidene fluoride (PVDF) electrospun membrane, unmodified cellulose nanofiber (CNF) based PVDF membrane, and Meldrum's acid (2,2-dimethyl-1,3-dioxane-4,6-dione) modified CNF-based PVDF membranes against the Fe2O3 nanoparticle filtration and crystal violet (CV) dye adsorption. Herein, we introduced a facile method to produce a unique green adsorbent material from cellulose nanofibers (CNFs) via a nonsolvent assisted procedure using Meldrum's acid as an esterification agent to enhance the adsorption toward positively charged crystal violet dyes. Most of the surface modifications of CNFs have been done using toxic organic solvents like pyridine, dimethyl acetate, (2,2,6,6-tetramethylpiperidin-1-yl)oxyl (TEMPO), etc. So far, this is the first report on the surface modification of cellulose nanofibers via a nonsolvent assisted procedure. Both CNF-based PVDF membranes were prepared by successive coating of modified and unmodified CNFs on to the surface of a PVDF electrospun membrane. All the demonstrated membranes showed high filtration capacity against the Fe2O3 nanoparticles. With the 10 mg/L of crystal violet (CV) aqueous solution, CV adsorption of PVDF electrospun membrane, and unmodified CNF-based PVDF membrane was around 1.368 and 2.948 mg/g of the membrane respectively, whereas it was 3.984 mg/g of the membrane by Meldrum's acid CNF-based PVDF membrane. The demonstrated Meldrum's acid modified CNF-based PVDF membrane was proven to be the efficient media that can concurrently eliminate the Fe2O3 nanoparticles and CV dyes from the water. The investigation into the surface chemistries of CNFs beyond the adoption of toxic solvents can enhance the economic usefulness of the process and also yield a new eco-friendly adsorbent material that is agreeable to adsorbing various toxic pollutants.

Surface-engineered nanocellulose towards improvedkinetic stability of Pickering emulsions

Caio Gomide Otoni[1]

[1]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais*)

e-mail: caio.otoni@ufscar.br

Surfactantless yet metastable multiphase systems are increasingly arousing scientific and technological interest. In particular, when stabilized by solid particles sitting at the oil/water interface, Pickering emulsions offer high kinetic stability and tunable rheological behavior. We herein isolated cellulosic nanostructures from biomass engineered their surface chemistry towards increased interfacial activity. Cellulose nanofibrils (CNF) were regioselectively esterified via imidazole-catalyzed reactions using acetic or isobutyric anhydrides. Introducing the hydrophobic ester moieties −acetyl and isobutyryl, respectively− at functionalization degrees of 0.6 to 1.0 mmol g-1 −confirmed by NMR, ATR-FTIR, and inverse gas chromatography− altered the rheological profile of sunflower oil-in-water Pickering emulsions and led to superior metastability. The interfacial energy betweena drop of aqueous CNF suspension and sunflower oil was reduced from 24 ± 1 mN m−1 byca. 15% (unmodified CNF), 22% (acetylated CNF), and 20% (isobutyrylated CNF). Likewise,the contact angle between water and films cast from the aforementioned CNF samples was increased from 26º to 52º and 61º, respectively. While our surface hydrophobization approach might stand by itself for O/W emulsions, our group took advantage of the netnegative charge of the oil droplets to promote its electrostatic complexation with cationicCNF decorated with quaternary ammonium moieties. We show that more than a single mechanism is at play when kinetically stabilizing Pickering emulsions using nanocellulose, at least chemical compatibility, electric charge, and continuous phase thickening.

Use of algae biomass to obtain nanocellulose and technological applications

Neftali Lenin Villarreal Carreno[1], Luiza Ribeiro Santana[1], Alaor Valério Filho[1], Guilherme Kurz Maron[1], Érica da Costa Campos[1], Claudio Martin Pereira de Pereira[1]

[1]Universidade Federal de Pelotas

e-mail: nlv.carreno@gmail.com

Currently, the use of renewable resources such as biomass has been increasing [1]. Seaweed is one of those renewable resources that have polysaccharides, lipids, vitamins and minerals in their cellular structures. However, only 50% of the various existing species have been identified and studied [2]. This characterizes algae biomass as an important raw material for several technological applications. Among the materials that make up this raw material, cellulose is undoubtedly of great interest, as it is widely used for various industrial applications. Since then, it has received great attention mainly due to its economic advantage. The extraction of cellulose fibers from algae has been considered a great alternative in the context of environmental maintenance, and has support for the growing market demand [3]. In the last two decades, nanocellulose has received much attention due to its renewable nature and properties such as biodegradability, biocompatibility, mechanical strength, lightness and high surface area [1]. Therefore, in this study, it is proposed the extraction of nanocellulose from macroalgae and characterization regarding its chemical and morphological structure. The results of Fourier transform infrared spectroscopy revealed that the employed methodology was effective for obtaining nanocellulose. The electron microscopy images showed the presence of fibers with a diameter on the nanometric scale.

Cellulose/Graphene Oxide Composites: rheological characterization of dispersions and mechanical properties of selfsustained films

Cibele Carneiro Pessan[1], Juliana da Silva Bernardes[2,3], Sílvia Helena Prado Bettini[4], Edson Roberto Leite[2,5]

[1]Nanox Tecnologia SA (*P&D*) , [2]Brazilian Center for Research in Energy and Materials, [3]Brazilian Nanotechnology National Laboratory, [4]Federal University of Sao Carlos, [5]Federal University of Sao Carlos (*LNNano*)

e-mail: cibele.pessan@ppgcem.ufscar.br

There is much interest in developing environment friendly packaging materials, especially considering the spike in e-commerce, delivery services, and the use of single-use disposable packages in the last years. Cellulosic materials allow for the production of strong biodegradable films, while further contributing to the circular economy when sourced from regional crop byproducts.[1] In this work, composite dispersions of nanofibrillated cellulose and graphene-oxide were prepared by microfluidization, after the TEMPO-mediated-oxidation reaction of cellulose pulp extracted from sugarcane bagasse. Rheological tests in oscillatory and permanent regimes indicated that the composite dispersions presented thixotropic gel-like behavior. It was possible to produce uniform selfsustained composite films from tape-casting process, with graphene-oxide content of 1 and 5 wt%. Tensile testing showed that the presence of graphene-oxide enhanced the mechanical properties of the films. The addition of 1 wt% of graphene-oxide content doubled the elastic modulus value and increased the tensile strength of the films in 85%. The mechanical enhancement is attributed to the formation of an interconnected structure between the nanocellulose fibers and the graphene-oxide.[2]

e-mail: g197699@dac.unicamp.br

The excessive use of petroleum-based plastic packaging has raised concerns about its environmental impacts, leading to research on sustainable and economically viable bionanocomposites. However, there are still challenges related to the intrinsic characteristics of some biopolymers that differ substantially from polyolefins, in terms of mechanical properties and water affinity. To address these issues, cellulose nanocrystals (CNCs) functionalized with natural rubber latex (NR) were explored as an effective alternative to enhance mechanical and physical properties of biopolymers. The functionalization process was developed by applying the freeze-drying method, which was inspired by the ice-templating approach to obtain nanocellulose-based aerogels. The effectof the functionalized nanofiller mass percentage in the biopolymer matrix, the NR content inthe nanofiller, and the nanofiller preparation method were evaluated for their impact on the mechanical and water vapor permeability (WVP) of bionanocomposites. The bionanocomposite films exhibited visible light transparency and mechanical properties comparable to conventional packaging such as polyethylene and polypropylene. The films also exhibited low WVP, indicating that they could serve as a significant barrier to other gases. These findings indicate a promising avenue for the development of a new generation of green nanofillers that can be conveniently hydrophobically tailored to suit various biopolymer matrices via different processing methods. Acknowledgement Fapesp process 20/08651-4.

Large-scale graphene synthesis using lignin asprecursor

Joyce Rodrigues Araujo[1], Oleksii Kuznetsov[2], Alexander Martins Silva[1], Braulio Soares Archanjo[2], Renata Simao[3]

[1]Instituto Nacional de Metrologia, Qualidade e Tecnologia, [2]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*DIMAT*) , [3]Universidade Federal do Rio de Janeiro

e-mail: jraraujo@inmetro.gov.br

In this work, a new approach to the synthesis of lignin-derived nanocarbon crystals based on lignin depolymerization is proposed. The lignin chemical structure was modified through a controlled routine, which was based on sequential UV light irradiation, hydrothermal carbonization in autoclave, vacuum degassing, pyrolysis and mechanical exfoliation [1]. After these steps, it was obtained a lignin-based nanocarbon with a sp2-hybridized nanoporous framework structure. The used catalyst-free route resulted in high nanocarbon yields and turns out to be an eco-friendly strategy of a synthesis of low-cost carbon material. The characterization of the lignin-derived nanocarbon was carried out using X-ray diffraction measurements, infrared, Raman and X-ray photoelectrons spectroscopies analyses, while its morphology was evaluated by scanning and transmission electron microscopy. Chemical spectroscopic and microscopy studies showed that the pre-treatment steps were crucial to produce, after the pyrolysis, a lignin nanocarbon phase composed of ordered structural domains with the apparent lamellar morphology of randomly oriented carbon sheets. In contrast, the final material of not pretreated samples, after pyrolysis, consisted of a mixture of ashes and lignin nanocarbon with much more disordered structure. We believe that the approach to lignin’s treatment proposed here has good prospects as a large-scale production method of a material similar to reduced graphene oxide. The proposed approach may be adapted to various biomass feedstocks with aromatic groups’ content suitable for their high yield polycondensation.

e-mail: francisco.torres@usp.br

Gellan Gum (GG) is a natural polysaccharide that can be modified to suit different applications [1], including the production of biocompatible hydrogels. In this work, GG was combined with sericin (SS), a protein that is a residue of fibroin extraction in silkworm cocoons, to create a functional composite. This material showed interesting mechanical and optical properties, such as the ability to reproduce patterns on its surface and angle-dependent iridescent colors, which make it useful for various applications such as sensors, random lasers, and structural color systems [2]. In parallel, the GG matrix is being modified with 3-glycidyloxypropyltrimethoxysilane (GPTMS) in order to enable the gelation of this hybrid system via photopolymerization. Both modified systems were doped with lanthanide ions, important in the development of photonic devices due to their distinguished luminescent properties. These interactions with Eu^{3+}ion showed an interesting sensitization effect, resulted in an increased emission intensity and longer lifetime of the excited state [3]. Additionally, 3D printing technique is being used to manufacture three-dimensional multilayer structures from these photopolymerizable materials, allowing for the creation of high-precision sensors and other devices with a wide range of applications in nanotechnology.

e-mail: marcos.lorevice@lnnano.cnpem.br

Nanocellulose-based aerogels have been reported as an eco-friendly alternative for water remediation (organic pollutants, heavy metal ions, and dye, e.g.) due to their highly porous network, large surface area, renewability, and biodegradability. However, cellulose nanofibrils (CNF) structures are unstable in aqueous media due to their high hydrophilicity, demanding chemical (or physical) crosslinking to maintain aerogel structure to avoid disassembling of aerogel 3D network in water. To overcome these drawbacks, natural rubber latex (NR) has been incorporated into CNF porous structures to improve wet resilience, enhancing structural resistance in aqueous media. Thus, aerogels comprising CNF and NR were developed. The heavy metal adsorption and CNF/NR ecotoxicity were assessed herein. Oxidated CNF-isolated from sugarcane bagasse was mechanically blended to NR to produce oxi-CNF/NR-based aerogels physically crosslinked with NR particles. The oxi-CNF/NR aerogels were obtained through the ice-templating protocol. They exhibited heavy metal adsorption capacity ranging from 108 to 420 $mg \cdot g^{-1}$, showing ~70 % removal capacity over the reuse cycles.[1]Furthermore, the ecotoxicity tests indicated, for the first time, not only that oxi-CNF/NR effectively remediated *Daphnia smilis*reconstituted water contaminated with Cu (II) and mitigated the toxic effect of Cu (II) at exposure over 60 ugL-1 close to the environmental scenario, but also the non-toxicity of oxi-CNF/NR by itself. Thus, these findings show oxi-CNF/NR aerogels as a promising, non-toxic, eco-friendly alternative for environmental remediation. Acknowledgement Fapesp process 2020/08651-4.

Spectroscopic studies of a composite from Eu^{3+}-doped cellulose nanocrystals/fibroin for luminescent cholesteric film production

Pedro Henrique de Lara Sanches[1], Francisco Recco Torres[2], Molíria Vieira dos Santos[3], José Maurício Almeida Caiut[2]

e-mail: pedro_sanches@usp.br

The synergy of the luminescent behavior of lanthanide ions (Ln^{3+}) with the physicochemical properties from cellulose nanocrystals (CNC), i.e., crystalline domains with strong intermolecular interactions [1], and silk fibroin, a protein with excellent mechanical and optical properties [2], play an important role on the development of new functional materials and photonic development. In this work, different routes to obtaining CNC were studied; in addition, the interaction of Eu^{3+}allowed us to study the coordination environment, aiming the production of different structural materials in order to generate photonic devices with color tunable in response to external action [3]. The objectives of this work were centered on the preparation and study of the Eu^{3+}-doped CNC, resulting in a film with iridescent characteristics, followed by the introduction of fibroin to obtain CNC-fibroin films. Photoluminescence studies have confirmed a better intensity emission from $Eu^{3+}$when excited by energy transfer from the cellulose structure. High values of pH in the film's preparation have provided more transparent and flexible materials, as well as an improvement in the emission parameters. Finally, further studies are been carried out for better knowledge about the coordination of Eu^{3+}ion at CNC structure, aiming to keep the cholesteric structure even after fibroin interaction.

Base-catalyzed production of fatty acid oligomers from castor oil

Lucas Natã de Melo[1], Simoni Margareti Plentz Meneghetti[2], Mario Roberto Meneghetti[2], Janaína Heberle Bortoluzzi[2]

[1]Universidade Federal de Alagoas (*IQB*) , [2]Universidade Federal de Alagoas

e-mail: LUCASNDM@OUTLOOK.COM

Estolides are oligomers composed of fatty acid (FA) monomers linked by mid-chain secondary ester bonds. These molecules can be synthetized from triacylglycerols (TGs), monoesters or free FAs and their size and properties depend on their degree of oligomerization and on further functionalization of the oligomer. The improved physico-chemical properties that the formation of estolides provide to natural fatty acid sources, such as vegetable oils, give to these special esters a wide range of applicability (e.g. base oils, lubricant additives, food emulsifiers and cosmetic formulations). Mineral acids, such as perchloric acid, and lipases are usually employed as catalysts for the production of estolides from unsaturation or oxygen-containing groups present in the aliphatic chains of FA bodies [1]. In this work, it was observed that the hydroxyl group present on the 12th carbon of the ricinoleic portion of castor oil (CO) acts as a transesterification agent when this oil is treated under chemical interesterification conditions (heating in the presence of a strong base as catalyst). Increases in viscosity in relation to the original oil (max. 146%) and HPLC and 13C NMR determinations confirmed the formation of acyl-glycerol estolides. Estolide numbers (EN) from 0.00 to 3.99 were obtained as a way to assess the degree of oligomerization for all samples studied. Due to the characteristics of the obtained material, its potential application as lubricants was investigated. In relation to the estolides reported in the literature and commercial lubricants with similar viscosities, the products obtained in this work presented advantages regarding the production process (in terms of number of reagents and reaction time) and most of the physical properties evaluated (pour point, flash point, ASTM color, viscosity index) attesting to the potential of industrial application of these materials.

A kombucha é uma bebida elaborada a partir do chá adoçado da Camellia sinensis fermentado com uma simbiose de bactérias e leveduras. Durante sua fermentação é formado um filme de celulose bacteriana (CB) na superfície do líquido chamado SCOBY(Symbiotic Culture of Bacteria and Yeasts) [1]. A celulose é o material orgânico mais abundante na natureza, e pode ser de origem vegetal, bacteriana ou animal, não diferindoem sua estrutura molecular e química. A celulose vegetal é a mais utilizada pela sua maiordisponibilidade e facilidade de obtenção, porém exige etapas intensas de purificação parasua utilização. Com isso, o objetivo deste trabalho é o reaproveitamento da CB do SCOBY,proveniente de resíduo industrial da produção de kombucha. Diferentes processos de obtenção, como por hidrólise ácida, mercerização e alcalinização tornam-se de grande valia para estudar possíveis aplicações do produto de acordo com suas propriedades. As análisesrealizadas nas CB extraídas foram composição centesimal e microscopia eletrônica de varredura (MEV). A quantidade de CB extraída foi acima de 90% para hidrólise ácida. Nasmicrografias observou-se que os tratamentos de mercerização e alcalinização foram insuficientes para separar as fibras, apresentando alto teor de carboidratos. As micrografiasdas amostras obtidas por hidrólise ácida mostraram comprimento de nanofibras. Assim, asnanofibras de celulose, de acordo com as análises físico-químicas realizadas e MEV, apresentam vantagens tecnológicas em relação à celulose vegetal [3]. References:[1]CHEN,C.;LIU,B.Y. CELLULOSE-BASED HYBRID MATERIALS FOR DELAYED DRUG RELEASE IN WOUND DRESSINGMATERIALS

Troy C. Breijaert[1], Vadim Kessler[2], Gulaim A Seisenbaeva[3]

[1]Swedish University of Agricultural Sciences / Sveriges Lantbruksuniversitet (*Department of Molecular Science*) , [2]Swedish University of Agricultural Sciences / Sveriges Lantbruksuniversitet (*Molecular Sciences*) , [3]Swedish University of Agricultural Sciences (*Molecular Sciences*)

e-mail: troy.breijaert@slu.se

Wound management is critically important in order to prevent wound infection and to facilitate the healing process. Traditional passive wound dressing material acts as a physical barrier to cover the wound, thereby lowering the chance of an infection. These wound dressing materials lack inherent antibacterial properties and/or wound healing properties. With the emergence of nanotechnology, methods have been explored in order to develop “active” wound dressing materials which stimulate tissue regrowth or provide an antibacterial effect. Nanocellulose has been of interest as a potential wound dressing material due to its beneficial properties (e.g. gas permeability, exudate removal), however it lacks antibacterial properties. Efforts have been made to combine antibiotics with nanocellulose materials, however these typically show low retention and rapid release of antibiotics. Effort has been made to control the release of antibiotics from nanocellulose materials by incorporating metal oxide nanoparticles. These particles are generally considered bio-compatible, with high affinity for antibiotics and pharmaceuticals. In this way a cellulose-based hybrid material was produced which permitted the release of the broad-spectrum antibiotic Tetracycline controlled by daylight.[1] A bacterial cellulose-based dressing material was modified with metal oxide nanoparticles to facilitate the delayed release of Tetracycline. Finally, a hybrid material was prepared for the controlled release of ampicillin[2]. Incorporating metal oxide nanoparticles into nanocellulose-based materials offers an approach to functional, biocompatible, hybrid materials capable of delaying drug release, which may be used as “active” wound dressing material.

Chemical-enzymatic conversion of ferulic acid intoepoxy resins: a renewable model to produce thermosetting materials

Henrique César Pereira Coelho[1], André Ferraz[2]

[1]Escola de Engenharia de Lorena - Universidade de São Paulo (*Biotecnologia*) , [2]Escola de Engenharia de Lorena - EEL/USP (*Departamento de Biotecnologia Industrial*)

e-mail: henrique_coelho@usp.br

Epoxy resins are thermosetting materials used in various applications such as adhesives, coatings and composites. Industrially, epoxy resins are produced based on bisphenol A, a petrochemical feedstock. This study aimed to develop a model of production of epoxy resin from ferulic acid, a renewable organic acid that can be obtained from plant biomass. Ferulic acid was dimerized by enzymatic oxidation using laccase [1], generating a dimer structurally analogous to bisphenol A. Ferulic acid consumption during reactions was measured by reverse-phase liquid chromatography. The reaction product mixture was subjected to an epoxidation reaction with epichlorohydrin to functionalize free phenolic hydroxyls with epoxy groups, with reaction efficiency monitored by differential UV spectroscopy. The epoxilated diglycidyl ether dimer was cross-linked with triethylenetetramine. The enzymatic oxidation reaction consumed all ferulic acid and formed several products, mainly the β-β dimer analogous to bisphenol A. The epoxidation reaction fully consumed the phenolic hydroxyls, confirming the functionalization with epoxy groups. The crosslinking of diglycidyl ether dimer with amine resulted in the formation of a glassy material with rigid characteristics, similar to commercial epoxy resins. The results of this study indicate the possibility of using a renewable feedstock for epoxy resin production as an alternative to the petrochemical route.

The disposal of untreated effluents in water bodies has caused serious impacts to aquatic biota, consequently making the water inappropriate for human consumption. In an attempt to mitigate the adverse effects, researchers are developing filter membranes from renewable sources [1,2]. The present work aims to develop filter membranes functionalizing cellulose nanofibrils (CNFs) for the removal of aquatic pollutant thus, the etherification reaction was carried out with a suspension of CNFs (3%) and the etherifying agent 2-aminoethyl hydrogen sulfate. Based on the 2^2 factorial design, four reactions were performed varying the temperature and reaction time. The chemical characterization was done using the Fourier transform infrared spectroscopic technique (FTIR), potentiometric titration, elemental analysis (AE), atomic force microscopy (AFM) and X-ray diffraction (XRD). The evidences that the chemical species under study was inserted in the CNFs are the increase in the intensity of the bands in the region of 2927 cm^{-1} and 2850 cm^{-1}, attributed to νasCH2 and νsCH2 and also the presence of other less intense bands attributed to the amino group; through potentiometric titration calculated the percentage of amino group (0.041%) and the degree of substitution (0.004); and 0.452% N (EA). To corroborate the initial results, the next steps will be to carry out pollutant removal tests.

The cultivation of macroalgae has stood out among the world's aquaculture sectors due to the transition to a low-carbon economy. In this sense, seaweed samples have the potential to be used as raw material for obtaining cellulose. Algae cellulose was first described in 1885. Since then, it has received great attention mainly due to its economic advantage. Cellulose extraction from the Chilean seaweed Ulva lactuca biomass was carried out following the methodology proposed by Paniz et al. [1]. After being harvested, the seaweed biomass was submitted to a pre-treatment of drying (35°C, 24h) and milling (knife mill). Then, it was forwarded to the desalination steps using deionized water at 110°C and removal of extractives using a Soxhlet system (toluene/ethanol at 7h). Finally, the sample was submitted to the following treatments: alkaline and bleaching using 5% NaOH and 0.1M $NaClO_2$solution, respectively. The sample was characterized using Solid-state nuclear magnetic resonance - 13C-CP-MAS. The cellulose extracted from the seaweed sample showed the typical signals of cellulose anhydroglucose carbon units at 105.7 ppm (C1), 89.8and 84.6 (C4), a large signal centered at 75.7 ppm (C2, C3 and C5) and 65.5 and 63.8 ppm(C6). Although peaks indicative of amorphous cellulose are more intense at C4 and C6 at 84.6 and 64 respectively, signals at 89.8 and 65.5 that correspond to crystalline cellulose were also detected. The cellulosic material was obtained without traces of impurities. Thus, the methodology proposed in this work was efficient in the extraction of cellulose from Ulva lactuca.

Coffee silverskin (CSS) is a thin tegument covering the coffee bean, and it is a by-product of coffee industry. Cellulose can be isolated from CSS to obtain cellulose fibers that could be incorporated into a polymer matrix, resulting in final reinforced products with high added value. Poly(butylene adipate-co-terephthalate) (PBAT) is a biodegradable polymer that can be used in the packaging sector, but its lower thermomechanical properties compared to other non-biodegradable polymers limits its use. In this work, alkali pretreatement was carried out on CSS fibers, followed by steam explosion. The cellulose fibers were incorporated into the PBAT matrix through melt fusion using a double-screw mini extruder (Minilab Rheomex). The properties of particles were evaluated by X-ray diffraction (XRD) and Fourier-transformed infrared spectroscopy (FTIR). Neat PBAT and its composites containing the same amount (2.5 wt.%) of different fibers (original CSS, pretreated CSS, pretreated, followed by a 2 bar-steam exploded-CSS and pretreated, followed by a 4 bar-steam exploded-CSS) were evaluated by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The results of FTIR and XRD showed that alkali pretreatment and steam explosion had removed some of the amorphous components of CSS. The results of TGA and DSC showed same thermal stability (Tonset of around 375 ºC) and an increase in the crystallinity index (2.9%) of composites when compared to neat PBAT.Acknowledgments:The authors would like to acknowledge the financial support by CAPES and CNPq.References:[1] Murthy, P. S.; Gouveia, R. F.; Lona, L. M. F. An Overview on Properties and Applications of Poly(butylene adipate-co-terephthalate)-PBAT Based Composites. Polymer Engineering and Science, v. 59, n. 2, 2019.

Development of sustainable filaments for 3D printingfrom PLA and modified Kraft lignin

Nathalie Minako Ito[1]

[1]Entropic Solutions - Technologies from Biomass Ltda.

e-mail: nathalie.minako@gmail.com

Despite being widely used in fused deposition modeling printing, poly(lactic acid) (PLA) has some mechanical limitations, such as low elastic modulus and excessive fragility, which restrict its use in functional applications [1]. In addition, its high cost compared to other types of filaments reduces its competitiveness compared to other available materials. In this sense, the inclusion of lignin can be an interesting strategy, since this biopolymer is an abundant component of biomass, obtained as a by-product of pulp processing and that does not compete with crops [2]. In this work, kraft lignin was chemically modified by esterification reaction with acetic anhydride and mixed with PLA using a twin-screw extruder to obtain a PLA/modified lignin blend. The acetylation reaction was evaluated combining the FTIR-ATR and DSC analysis, indicating both the successful modification of the kraft lignin and that the acetylated KLA will be suitable for incorporation into PLA. The modified lignin was incorporated into the PLA matrix, producing filaments of the PLA/modified lignin blends with a mass fraction of 70/30, respectively. DSC and DMA analysis (tanδ curve) suggested good compatibility between PLA/lignin, despite the high content of the latter. Combined analysis of rheology and DMA showed that PLA/modified lignin blends have desired characteristics for 3D printing, which are high G'' and h* in quasi-static conditions and low G'' and h* at high frequency. The final test of the filaments was performed on the 3D printer, in which it was possible to obtain printed samples.

The search for a healthier diet and the consumption of products with fewer preservatives and materials of synthetic origin is a current reality with a growth trend in the coming years. Kombucha can be a great alternative for a healthier diet and has many other benefits for human health.

The consumption growth and consequently the increase in the production of the beverage, the manufacturing chain inevitably generates rejects and residues, such as SCOBY disposal after successive productions due to the drop in productivity in terms of the capacity of cellulose synthesis and generation of acids through bacteria and fermentation capacity of yeasts.

The reuse of this waste can contribute economically and environmentally to the production process as a whole, for example, the use to obtain cellulose nanostructures in different segments, such as bio-sorbent cellulose film for effluent treatment, skin dressings or thin films for drug delivery.

The objective of this work is to obtain bacterial cellulose from homemade Kombucha waste through chemical bleaching treatment. Characterization of bacterial cellulose regarding its chemical composition, crystallinity index, thermal properties, and morphology in macro, micro, and nanostructured scales (nanocellulose). Obtaining bacterial cellulose micro and nanofibers through mechanical shear and characterization of bacterial cellulose and the possibilities of applying this material in superficial adhesives for repellent activity.

Fluorescent Carbon Dots Synthesized from Kraft Lignin via Hydrothermal Process

e-mail: rosinaldo.aparicio@ufpr.com

Carbon dots (CDs) are photoluminescent nanomaterials with various technological applications, such as nanomedicine, sensors, biosensors, photocatalysis, organic solar cells and others [1-2]. However, their widespread use is hampered by the lack of potential raw materials with adequate [2]. This study aimed to produce CDs using Kraft lignin (KL), a co-product of the pulp and paper industry that is widely available in large scale. The CDs were synthesized via a hydrothermal process using KL and ethylenediamine as a dopant in distilled water. The produced material was a dark solution with a high dispersibility in water and a pH of 10.5. Under UV-A irradiation, the solution exhibited a blue-green color with a high degree of fluorescence. The UV-Vis analysis revealed a characteristic band at 277 nm, indicating the presence of the aromatic π-π* group, and a shoulder between 310-340 nm, suggesting n-π* of the C=O groups. The FTIR analysis confirmed the presence of functional groups of aromatic refusion of KL fragments. The zeta potential measurement indicated a surface charge of -31.7 mV at basic pH. The simple reaction process and the presence of negative charges indicate the potential application of these CDs for detecting heavy metal ions. This study demonstrates the possibility of producing carbon dots from KL, which could lead to a new direction for high value-added applications of this widely available co-product.

e-mail: letizia.verdolotti@cnr.it

In the last decades, the development of renewable materials and eco-friendly processes have gained much interest from researchers aiming to minimize the carbon footprint as wellas fossil fuels dependence. On this account, the replacement of the widespread petroleum-derived materials with greener and sustainable ones, had been widely performed by research communities. Nano-Crystalline Cellulose, CNCs is widely used as filler in polymer composites due to its high specific strength, tensile modulus, aspect ratio and in compliance with the principles of circular economy [1]. However, its hydrophilicity makes its dispersion complicated in hydrophobic polymeric matrices, resulting in aggregate structures, which compromise its reinforcing action. Here, the sytnthesis of modified CNCs via silanization in homogeneous media (N,N-dimethylacetamide/LiCl) and subsequently grafting with bio-based polyol is presented. Filler functionalization in homogeneous media allowed to graft up to 0.8 mmol of polyols per gram of CNCs. The polyol chemistry (i.e. molar masses and OH number) affects the functionalization effectiveness. On this account, bio-based composite Polyurethane foams, filled with 1-3 wt% of modified CNCs, were considered as case study and their chemico-physical, thermal, morphological and mechanical properties are investigated.

Abstract: Ensuring water quality and protecting aquatic life requires the removal of contaminants, and adsorption is a widely used, efficient, and cost-effective technique for water treatment, with many materials being studied for this purpose[1]. Nanocellulose and chitosan have demonstrated promising results as adsorbents for the removal of heavy metals, dyes, and pharmaceuticals due to their high surface area and unique properties. In a similar vein, the utilization of ethylenoxymethylenes and ethoxyacrylates has also shown potential for the adsorption of these contaminants[2]. These materials have been chemically modified through grafting to enhance their adsorption capacity and selectivity. This research area is still in its early stages, and further studies are needed to fully understandthe potential of these materials for water treatment applications. With the growing demandfor more sustainable and efficient solutions for contaminant removal, adsorbent materialshave become increasingly important for the protection of water and the environment as awhole[3].

Acknowledgments: We would like to thank CAPES for the financial support through the doctorate degree.

Industrial waste usage for technological applications has been gaining ground in different segments and applications. One of the prominent sectors is Material technology, where these residues can be used to obtain the raw material for obtaining fillers and reinforcement in thermoplastic polymeric materials. Cellulose has been used as a source of study and has several applications in materials, such as reinforcement, load, or chemical surface modifications. The nanocellulose, which is obtained from different chemical, mechanical and biological processes, can be in the form of cellulose nanofibrils (CNFs), which are present in crystalline and amorphous regions along it, and cellulose nanocrystals (CNCs) which reveal only the crystal region. The material in this work is malt bagasse, which is currently the waste generated in the beer industry by bulk and shows no alternative reuse and application in Material technology. Was determined the chemical composition of the fibers and applied a chemical bleaching process to remove components such as lignin and hemicellulose in preparation for the fibers for obtaining nanocellulose through acid hydrolysis. Hydrolysis was performed using H2SO4 at two concentrations, 44% (w/w) and 64% (w/w), at temperatures of 40°C and 50°C for the samples subjected to the acid solution at 44%, besides that, it was used at 40°C, 50°C and 60°C for samples with 64% solution. For thesamples, 44/40 and 44/50 were obtained CNFs and for the 64%, the result obtained wasCNCs. Natural and bleached fibers, along with nanocellulose, obtained through different concentrations of H2SO4 and temperature were characterized by Fourier Transform Infrared Spectroscopy (FTIR), Atomic Force Microscopy (AFM), Scanning Electron Microscopy (SEM) and Field Emission Scanning Electron Microscopy (FESEM), X-Ray Diffraction (X-RD) and Thermogravimetry (TG).

Obtation and Characterization Kombucha Bacterial Cellulose: Biomedical Applications

Thaís Soares de Góes[1], Marcelo de Assunção Pereira-da-Silva[2], Daniel Komatsu[3], Aparecido Junior de Menezes[4]

e-mail: thaisgoes_ufscar@hotmail.com

Kombucha (KC), known as an ancient beverage of Asian origin, is a promising source of bacterial cellulose (BC), which can be obtained through fermentation processes, such as green tea and sucrose [1]. The BC has stood out due to its unique properties, such as purity, crystallinity, biocompatibility and tensile strength, supporting commercial applications in different areas. This work aims to produce the bacterial cellulose membrane of Kombucha (MCBK), through a symbiotic consortium of yeasts and bacteria, cultivated by the fermentation of green tea and sucrose, kept in a light-free environment, varying the growth time and thus, determine the best obtaining conditions. MCBK were characterized by optical microscopy, SEM, AFM, XRD and FTIR, in order to enable the development of high added value products for biomedical applications, such as skin dressings for the treatment of skin lesions and burns [2,3].

Acknowledgments: The authors to thank CAPES for the financial support.

e-mail: ludmila.candido@ima.ufrj.br

Bioplastics are attracting great interest from the scientific community and industry, emphasizing biodegradable polymers. Poly(butylene adipate-co-terephthalate) (PBAT) is of greater commercial interest among bioplastics, as it is a biodegradable material obtained from bioderived raw materials. It is reported in the literature that nanocomposites reinforced with nanocellulose have properties superior to those of the original polymers, such as excellent mechanical and thermal properties. However, one of the limitations of using nanocellulose as reinforcement in polymers is the low affinity between its structure and the polymeric matrix due to the high number of hydroxyls on the surface. In this work, nanocelluloses with different morphologies were modified by acetylation in order to improve the interaction between the fillers and the polymer. PBAT composites were produced with the acetylated fillers, as well as with them without treatment, via mixing in the molten state in a mini twin-screw extruder at 160 ºC for 7 min. The effectiveness of acetylation was confirmed by infrared spectroscopy (FTIR). The characterization of PBAT through thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) showed that the processing did not significantly alter the polymer properties. Scanning electron microscopy (SEM) confirmed that the nanocelluloses showed good interaction and dispersion with the polymer matrix. The addition of fillers did not cause a decrease in thermal stability but promoted an increase in the hydrophobic character of the samples, confirmed by the contact angle with water. Compared to the pure polymer, the composites generally did not decrease their performance, which is important for the desired application.

e-mail: samirmathias@gmail.com

Abstract: Surucucumira, a hapaxanthic tree, can be planted among others Amazon native trees providing shades and protection to slow growing species because of his fast growing, 10~20 meters of height and 20 centimeters of diameter in 2 years[1]. This specie's biomass chemical composition was inspected through TAPPI standards[2]. According to the analysis, lignin and alphacellulose accounted for around 39% and 31% of the total content. FTIR measurements showed the removal of lignin and hemicellulose from the raw fibers without breaking the glycosidic bond of the cellulose, corroborating with the SEM micrographs, that showed the released fibers (fibrillation) after the bleaching process. TGA showed the dependence of intermolecular and intramolecular relationships for a better, or worse, thermal stability of the samples. X-ray diffraction patterns reiterate type I cellulose for theraw/holo samples, and type II cellulose for the bleached ones. AFM showed the successfullyextraction of the cellulose nanocrystals (CNCs) and by calculating the aspect ratio and thespecific surface area it was shown that these CNCs might improve barrier properties onpolymers matrices[3].

Acknowledgments: We would like to thank CAPES for the financial support through the master degree, the Amazon Phoenix Project (Projeto Fênix Amazônico) for the fibers' donation and IFSC/USP for the AFM measurements.

Polysaccharide hydrogels are hydrophilic compounds that make up a three-dimensional polymeric network capable of absorbing large amounts of water while maintaining its structural integrity. They are classified as superabsorbent when they can absorb water up to one hundred times their mass [1]. As bacterial cellulose has hydrophilic groups on its surface, it contributes to the water-retaining properties of the hydrogel. This work aimed to synthesize superabsorbent hydrogel from babassu mesocarp (HMB)| and bacterial cellulose (HCB). The samples were characterized by spectroscopy in the infrared region with Fourier transform, swelling test, and toxicity against Artemia salina. HMB showed characteristic vibration of the acrylamide monomer around 1670 cm-1, and the polyacrylamide bands masked the starch bands. For HCB, bands around 1335 and 1162 cm-1, corresponding to the asymmetric C-O-C stretching, are characteristic of cellulose II [2, 3]. The swelling capacity of the hydrogels was greater than 300 g/g. The ecotoxicity test against Artemia salina showed that after 24h, the number of live nauplii was greater than 80% in all concentrations used. After 48h, the number of live nauplii remained the same. The results presented showed the formation of the hydrogel and its non-toxicity, making it desirable for agriculture and drug adsorption applications.

Additive manufactured microfluidic device for electrochemical detection of carbendazim in honey samples

Bruno Campos Janegitz[1], Luiz Ricardo G. Silva[2], Jéssica S. Stefano[2], Robert D. Crapnell[3], Craig E. Banks[3]

[1]Universidade Federal de São Carlos - Campus Araras (*DCNME*) , [2]Univerdade Federal deSão Carlos, [3]Manchester Metropolitan University

e-mail: brunocj@ufscar.br

The use of pesticides is one of the primary means of protecting crops. However, this class of compounds can be highly toxic to the environment and humans [1]. Therefore, developing analytical devices for monitoring pesticides such as carbendazim in food sources is of paramount importance [1]. In this context, 3D-printed complete electrochemical platforms have gained increasing prominence in the literature, as it combines the qualities of electrochemical devices with the advantages and characteristics of 3D printing technology [2]. Thus, the present work presents the development of a paper-based microfluidic device coupled to an additive manufacturing platform and electrochemical sensors (produced from lab-made conductive filaments based on carbon black) for the sustainable detection of carbendazim in honey samples. All quantitative analyses were performed on a microfluidic paper attached to the 3D printed device with the electrochemical sensors attached and the drop volume was 30 μL for all analyses performed. For the application of the microfluidic device, the electrochemical sensors were previously electrochemically treated and characterized. Subsequently, the pH of the supporting electrolyte and the operational parameters of the square wave voltammetry technique were optimized. The microfluidic electrochemical device presented satisfactory results for the analysis of carbendazim, in the linear range from 0.5 to 40.0 μmol L-1 with a LOD of 0.09 μmol L-1. The recovery test performed in honey samples showed values ranging between 92.4 and 108.8%. According to the results, the proposed microfluidic device demonstrated the advantages of employing sustainable and renewable materials.

Mineral nanoparticles as plant stress mitigation and growth promotion agents

Vadim Kessler[1]

[1]Swedish University of Agricultural Sciences / Sveriges Lantbruksuniversitet (*Molecular Sciences*)

e-mail: vadim.kessler@slu.se

Life has emerged and developed in constant presence of mineral nanoparticles (MP). Dissolution of tectonic silicate minerals, major components of the earth crust, leads continuously to formation of sand minerals, originally - in the form of nanoparticles. The latter are undergoing aggregation and growth forming micro and macro particles. Major sand minerals, originating from these reactions are common sand, SiO_2, iron oxides FeO_x, aluminium oxide-hydroxides, manganese oxides, MnO_x, and titanium dioxide, TiO_2. Other major fraction of sand is composed of calcium and magnesium carbonates. Beneficial effects of flooding rivers on crop growth have been well recognized in human history. The are usually explained to be partly due to the presence of MPs in the sediment, through their ability to adsorb and release nutrients and microelements.

In our studies we have demonstrated that in particular TiO_2MP can be generated by plants themselves on interaction of plant root exudates with soil minerals [1]. The beneficial role of MP was shown to be in particular due to their ability to enhance bacterial adhesion to the roots and formation of large clusters of plant growth promoting rhizobacteria (PGPR) [2], resulting in beneficial effects via plant stress mitigation. Another important mechanism of MP nanomaterials is nanozyme effect that can be used to regulate the concentrations of Reactive Oxyges Species (ROS) in plant tissues – a feature typical of iron oxides and ferrites [3]. Controlled oxidation of key amino acids mediated by MP as nanozymes can lead to improved synthesis of plant hormons improving biomass production [4]. These properties make MP attractive as additives in seed treatment for improved plant survival and growth.

The science of coordination compounds is very important for areas such as nanotechnology, biomedicine, agrochemicals, new materials, and others. In the agrochemical area, a molecule of biological interest, by being coordinated with metal, can increase the efficiency of the active principle and reduce its toxicity. Currently, copper (II) is used in a wide range of industrial processes, with remarkable biological importance in different types of organisms, as in plant photosynthesis and as an active center of certain proteins and enzymes. Studies have also shown that Cu (II) compounds coordinated to monoethanolamine (MEA) have antifungal action, improving the defense of plants against certain pests, such as in the formulation of wood preservatives, and have moderate antimicrobial activity too. The vibrational, electrochemical, and thermal properties of the monoethanolamine (MEA) complex were investigated by combining infrared spectroscopy and Raman at room temperature, assisted by density functional theory (DFT) calculations. Calculations on B3LYP and LANL2DZ (which contain ECP information) led to the identification of the minimums on the potential energy surfaces of the molecules. These calculations predicted the most stable conformer was predicted in relation to the dihedral angle H9-C4-N7-Cu1. A more precise understanding of the fundamental vibrational modes is obtained by comparing experimental and theoretical vibrational spectra, which also improves the interpretation of experimental Raman and infrared spectra. The vibrational attribution given in terms of potential energy distribution analysis (PED) leads us to a more comprehensive interpretation of the vibrational spectra of the investigated materials and electronic properties. Time-dependent DFT was used to derive HOMO and LUMO (TD-DFT). The gap energy, which was determined by comparing the HOMO and LUMO orbitals, was calculated at 0.786 eV

Antibiofilm activity and synergism of essential oils and antibiotics (oxacillin) encapsulated in electrospun fibers of cellulose acetate

Helinando Pequeno de Oliveira[1], Jarbas Freitas Amarante[1], Mateus Matiuzzi da Costa[2]

[2]UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO (*Ciência Animal*)

e-mail: helinando.oliveira@univasf.edu.br

The World Health Organization (WHO) has warned of the increase in contamination by food infected with microorganisms that affect about 10% of the population, with a high death rate. These data lead to great concern, as revealed by the increase in the use of chemical and synthetic products to minimize losses in processed and fresh foods, which contributes to bacterial resistance mechanisms against conventional antibiotics [1]. Thus, the use of alternative strategies to avoid/ minimize antibiotics in high concentrations is necessary to control the bacterial population. The objective of this work was to evaluate the in vitro antibacterial activity of electrospinning fibers of cellulose acetate associated with essential oils of clove, cinnamon and eucalyptus and their combinations (clove + cinnamon, clove + eucalyptus and cinnamon + eucalyptus) in addition to the association of essential oils with oxacillin. The response of the electrospun systems was evaluated using agar diffusion assays, the kinetics of time of death and the antibiofilm response of the modified fibers. The best experimental systems were fibers with clove essential oil in combination with cinnamon essential oil, which allowed the complete elimination of S. aureus from an initial concentration of 108 CFU/mL after 3 hours of treatment, showing even better results for inhibition of biofilm with a reduction of 47% and 65% for fibers with clove and with clove + cinnamon, respectively, confirming superior results for the use of essential oils reported in a new experimental system, which allows the high surface area of electrospinning fibers (in association with porosity) and the diffusion of oil along the fibers for the continuous action of the active compounds to be extended and applied in products such as wet wipes for bacterial removal.

e-mail: mariana.forini@unesp.br

Current agricultural practices are incipient and will not be able to meet the population's demand for food. In an attempt to change this scenario, agrochemicals are used in an exacerbated way. However, studies show that only about 0.1 to 10% of agrochemicals reach the target plant, with the rest being degraded or bioaccumulated in soil and groundwater [1]. Nanotechnology based on developing controlled release nanocarriers has been a promising agriculture technology since it contributes to reducing environmental impacts. However, challenges have arisen related to toxicological aspects, safety, as well as understanding the behavior and mechanism of action of nanocarriers in complex biological matrices. Therefore, advances in science have allowed the combining of individual nanoparticles into more complex and advantageous systems, also called supraparticles (SPs) [2]. In this study, a superhydrophobic surface was prepared to synthe SPs using the evaporation-directed synthesis method. Thus, hybrid SPs were synthed from zinc oxide nanoparticles (ZnO NPs), poly-epsilon-caprolactone nanocarriers containing magnetic nanoparticles (Fe_3O_4@OA NPs), and herbicide atrazine (PCL:ATZ:NPs Fe_3O_4@OA). Infrared Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM) analysis evidenced the presence of NPs inside the SP with spherical morphology. Moreover, Zn and atrazine were slowly released from the SPs. This innovative system opens up prospects for a new hybrid agrochemical delivery system. Acknowledgments: The authors acknowledge the FAPESP (#2022/03219-2 and #23/00541-3), CNPq (#427498/2018-0, #161360/2021-1), and CAPES for the financial support. References:

e-mail: iusseny.souza@ifmt.edu.br

Active packaging has become a promising source of research since a large part of the food has been infected by infectious agents such as bacteria, fungi and viruses still on the shelf. Simonkollite ($Zn_5(OH)_8Cl_2H_2O$) also known as zinc hydroxide chloride compound monohydrate, naturally found in German mines, is a derivative of Zinc Oxide corrosion with potential microbial activity [1]. Staphylococcus aureus is a bacterium that can cause diseases, infections, pneumonia, meningitis, and others, it was used in this work to testing that effectivity of biofilms. The objective of this work were the development of a bioactive film based on chitosan ⁄silica composite functionalized with nanoparticles of Simonkolleite (SK) and Simonkolleite silver (SK-Ag). In order to develop of the biofilm, tests were performed evaluating the concentration composite (0.75%, 1% and 1.5% m/m) and nanoparticles (1%, 2% and 5% v/v). These materials were characterizated by thermogravimetric analysis (TG), FTIR, scanning electron microscopy (SEM) and X-Ray Spectrometry (EDX). In order to evaluate the antibactericidal activity of the Composite SK5% and composite SK-Ag (5%) films, a test was performed to determine the antibactericidalactivity where the Staphylococcus aureus ATCC 25923 (Laborclin) strain obtained the antibacterial ratio of the control test groups that was performed by direct contact method,respectively after 1 hour with the standardized inoculum. Despite of numerical values of allnanocomposites showed antibacterial activity against S. aureus, the SK-Ag was 10% moreeffective due to the additional effect of Ag. In view of the above, the evaluated films havethe potential to be use as active packaging.

During fruit production, it is important to overcome the enormous challenge of controlling pests such as the fruit fly [1]. Therefore, this work developed an adsorbent material based on silica precursor and biopolymer (cotton línter purified), capable of controlling the releaseof semiochemicals [2]. This material was characterized by several techniques such as FTIR,SEM, XRD, EDX, BET and tested for the release of ethyl octanoate, which is one of the compounds present in the pheromonal mixture of the fruit fly. The material had an area of 340 m2/g and significant results in bioassays for the attractiveness of mated females of the Anastrepha Obliqua species, with an adsorption capacity of 213.5 mg/g and a release rate of 1,087 mg/h. The decomposition profile and thermal stability showed that the hybrid will resist the conditions to which it will be submitted in the field. With this, it is intended to produce a prototype of attraction and subsequent elimination that will be used in integrated management programs contributing to the population control of pests.

Easy production of corn zein micro- and nanospheres with the using of Ultrasound

Sergio Akinobu Yoshioka[1], Bruno Garcia de Oliveira Breda[1], Gabriel da Silva Florintino[1]

[1]Instituto de Química de São Carlos Universidade de São Paulo (*Grupo de Bioquímica e Biomateriais - Depto de Química e Fis.Molecular*)

e-mail: sergioy@iqsc.usp.br

Zein is a protein of the groups of cereal prolamins, in the case of this protein, found in greater quantity in the endosperms of corn grains, reaching around 8% in this region along with starch. In order to encapsulate the starch globules with the various types of zein, which together with carotenoids in the cross-section of the grains forms a vitreous material with zein and starch that is too hard to withstand physical damage in transports and insect attack. With the development of the extraction process by the group of crude zein from corn gluten bran, this work aims to prepare micro- and nanospheres of zein from this crude zein with the aid of ultrasound to verify if there is a reduction in at a temperature of 25°C. The results of scanning electron microscopy of the zein spheres showed that the reduced about 10% with s between 90 to 550nm. This reduction must be because of the ultrasound vibrations of the drops that can improved with the use of capillary of smaller diameter getting with higher concentration of the nanospheres close to 200nm. In these nanospheres, we want encapsulate jambolan extract to treat the symptoms of herpes zoster on the skin in the body of people affected by this infection, or encapsulate bioinseticides or biofertilizers to control delivery.

e-mail: dennypaula@alunos.utfpr.edu.br

There is a growing demand for the use of biocompatible and eco-friendly materials to compose parts of electrolyte-gated transistors (EGTs), since this class of devices can be applied in situations as e.g., artificial synaptic devices, basic building blocks in bioelectronics or biosensors. EGTs can operate as electrolyte-gated field effect transistors (EGOFET), being modulated by the gate field effect, or as organic electrochemical transistors (OECT), being modulated by the ionic current. In this work, it is depicted a sequence of measurements performed on EGTs with the following structure: gold electrodes with a gate in-plane, poly(3-hexylthiophene-2,5diyl) (P3HT) as the channel and commercial gelatin foil hydrated with deionized water or bovine milk as electrolyte layer. Gelatin is a natural protein from animal being also a bio-compatible and low-cost material as well as bovine milk. The electrical characterization was performed based on the typical transistor’s curves: transfer and output curves, added by a simple IxV curve [1]. Transistor measurements using only gelatin hydrated with deionized water was considered as reference measurements (base-line signal). When water is replaced by milk, it was observed that the EGOFET to OECT transition regime has been changed, being reduced by 0.1V, and that the leakage current through the electrolyte was increased. Even so, it was possible to carry out a sequence of measurements showing that the transistor structure with bovine milk operates in EGOFET and OECT modes depicting the typical transfer and output curves profile. These data open opportunities for future applications as a platform for sensing adulterated milk.

e-mail: gabriela.salzedas@unesp.br

Brazilian agriculture''s national and global significance coexists with the widespread use of pesticides. The production of sugarcane has established Brazil as a prominent player in the agricultural industry, with the state of São Paulo leading the country''s production. Furthermore, the mesoregion of Assis is noteworthy for exceeding the state''s average production. In this scenario, simazine (SI) and methyl parathion (PM) have been extensively consumed and they are among the 27 pesticides detected in river waters that supply the mesoregion of Assis. Although these pesticides are regulated by Law, their cytotoxic effects have been poorly explored on human health. Due to inhalation, the lung is a very vulnerable organ to such toxins and can be considered a target for the cumulative cytotoxicity of these pesticides. In this study, we have elucidated the cumulative cytotoxicity of the pesticides SI, PM, and their cocktail (mixture of these pesticides) on in vitro culture of cells derived from human lung carcinoma (A549). The cytotoxicity assays were performed by incubating A549 cells with two different concentrations of the pesticides and their cocktail (10-5 mol/L and concentrations regulated by Law) for 24, 48, 72 and 96 h. The results showed a reduction in cell viability with an increase in the incubation period, indicating a cumulative cytotoxicity of these pesticides over time. Moreover, higher concentrations of the pesticides exhibited a stronger cumulative cytotoxic effect of the cocktail, indicating a synergistic cytotoxicity. Thus, despite being released for use in sugarcane agriculture at concentrations regulated by Law, preliminary in vitro studies have shown the cumulative cytotoxic effects of these pesticides on lung cells. We shall investigate the morphological modifications and membrane permeabilization to obtain more evidence and a better understanding of the cumulative cytotoxicity of these pesticides. Enhancing the quality and microbiological control in controlled environment agriculture (CEA): Harnessingthe Ultraviolet Light (UV-C) treatment in hydroponic systems.

SHIRLY MARLENY LARA PEREZ[1]

[1]Univerdade Federal de São Carlos (*PPGBiotec*)

e-mail: s.mlarap@gmail.com

Plant microorganisms have the potential to benefit plant growth by producing natural antibiotics, but they can also spread diseases that impede growth due to competition for nutrients. Plant management and environmental contamination can lead to various types of contamination, causing infections and hindering plant growth (1). In hydroponic systems, fluid recirculation can spread microorganisms through water and infect crops (2) making it necessary to adopt decontamination methods. This study explores the use of UV-C light for microbiological control in hydroponic lettuce production in a controlled environment agriculture (CEA), examining the effects of its application. We studied the effects of UV-C light on the growth and biochemistry of hydroponic lettuce, including height growth time, pigment content, phenolic compounds, antioxidant capacity, and mineral levels. Samples exposed to UV-C light in the hydroponic fluid, were compared to control groups without UV-C application, under 18 and 20-hour photoperiods. Applying the UV-C decontamination system to nutrient solution promoted faster plant growth while maintaining or even increasing nutritional values compared to non-treated groups. That technique has significant potential for accelerating vegetable production, reducing production time, and enhancing the absorption and content of beneficial compounds.

e-mail: debora.antunes@unesp.br

Zinc deficiency is the most ubiquitous micronutrient deficiency problem in world crops. Hence, zinc fertilizers are used to prevent Zn deficiency and in the biofortification of several cultures worldwide [1]. However, novel technologies are emerging to create eco-friendly formulations of zinc that are cost-effective and less toxic to the environment. In this study, hybrid beads were fabricated using a blend of biopolymers such as alginate, cellulose, and lignin to encapsulate zinc nanoparticles (Zn NPs) to produce a Zn-controlled release system in the soil. The beads containing Zn-nanoparticles were prepared by the co-precipitation method and characterized by several analytical techniques [2]. Optical microscopy (OM) and scanning electron microscopy (SEM) analysis of hybrid beads showed spherical morphology and distribution of c.a. 3 mm. X-ray scattering spectroscopy (EDS) confirmed the presence of Zn nanoparticles uniformly distributed inside the beads with energy peaks in the range of 8.65 keV for Zn. Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD) indicated interactions between polymers and Zn NPs. In vitro release assays showed that Zn NPs-encapsulated in biodegradable beads can release zinc ions to the environment in a controlled way. Therefore, our system has the potential to change the bioavailability of zinc in the soil and may contribute to better absorption of micronutrients by plants.

Acknowledgments: The authors acknowledge the FAPESP (#2022/03219-2 and #23/00541-3), CNPq (427498/2018-0), and CAPES for the financial support.

e-mail: carolbatistin_@hotmail.com

Glyphosate (GLY) is a herbicide organophosphate, active ingredient of the Roundup® commercial formulation and present in hundreds of other agricultural pesticides. This organophosphate is a neurotoxic agent, also considered as potentially carcinogenic by the Agency International Committee for Research on Cancer (IARC).1 Faced with occupational exposure to GLY, it is necessary to develop filters that are efficient in its adsorption, aiming at the production of masks and personal protective clothing that avoid intoxication of farmers, especially chronic intoxication. Zirconium-based metalorganic frameworks have been showing excellent performance in the adsorption of GLY. In this work, MOF-808 was synthesized in-situ (FI) and ex-situ (FE) on cellulose fabric substrate (cotton fabric), subsequently tested in Roundup® brand commercial GLY adsorption, both in solution immersion and in aerosol tests. The presence of MOF-808 in tissue was confirmed by DRX and SEM. In immersion adsorption tests, the fibers removed 99.8% (FI) and 99.6% (FE) of GLY in solution after 3 hours of contact, while the unmodified fiber (FNM) achieved 10.2% removal. The Langmuir model showed the best fit to the adsorption isotherm obtained, reaching the maximum adsorption capacities (qmax) of 10.8 mg g-1 (FI) and 6.38 mg g-1 (FE). In aerosol tests, the composites showed increased efficiency by 73% (FI) and 87% (FE) compared to the performance of FNM, indicating that the presence of MOF-808 in the fabric increases its efficiency in adsorbing glyphosate. These results demonstrate the potential of cellulose-MOF composites in the development of personal protective equipments for manual application of GLY. Acknowledgements: To LabPetro and LUCCAR (UFES), BSTR (UFPE) and LQSN (UFF) for technical support. References: [1] Ferreira, C., Durán, R. & Faro, L. R. F. Toxic Effects of Glyphosate on the Nervous System: A Systematic Review. Int. J. Mol. Sci. 23, (2022).

Germination responses of Oryza sativa L. seeds by the application of sophorolipids derived from Starmerella bombicola

Silvio Silverio da Silva[1], Thiago Moura Rocha[2], Paulo Ricardo F. marcelino[2], Julio César dos Santos[2], Pedro V R S[2]

In order to foster more sustainable agricultural practices, biotechnology may play prominent role in the transition of vegetal monocultures to a more diverse agriculture aiming to preserve and assure biodiversity variability. In this context, biosurfactants (BSs) and specifically, sophorolipids (SLs) derived from yeasts such as Starmerella bombicola can affect the dynamics of cellular membranes which in turn may cause amendments in their permeability, fluidity as well as hydrophobicity [1]. These amendments may stimulate the immune system of plants and confer resistance to abiotic and biotic stresses [2]. In this sense, this study has aimed to evaluate the germination responses of Oryza sativa L. seeds by the employment of SLs treatment. Regarding the results, SLs in lower concentration (0,15 g/L) conferred notable improvement to the vigor of germination, total seeds germinated, the size and number of roots, and the dry total biomass compared to the control (H20). Thus, it is expected to contribute to the development of eco-friendlier bioproducts to promote sustainable agriculture worldwide.

Acknowledgments:This work is part of the project “INCT Yeasts: Biodiversity, preservation and biotechnologicalinnovation”, funded by Conselho Nacional de Desenvolvimento Científico e Tecnológico(CNPq), Brasília, Brazil, grant #406564/2022-1.

The application of free amino acids has multiple functions as biostimulants of plant growth and development. Particularly, the use of Tryptophan (Trp) has positive effects on crop growth and productivity, as well as mitigating the negative effect abiotic stress [1]. Nevertheless, tryptophan (Trp) is an aromatic chemical compound that is susceptible to photooxidation and degradation upon exposure to UV light, which give it limitations when it comes to ensuring its effectiveness on a productive scale [2]. Layered double hydroxides (LDH) belong to the class of anionic clays whose structure is based on layers similar to brucite (Mg(OH) [3]. Our working hypothesis is based on the fact that LDH functionalized with Trp (LDH-Trp) have high potential as a novel active compound for application purposes, since the functionalized nanoclays confer stability to the active principle. In the present work, an HDL of Mg-Al was synthesized by co-precipitation and subsequently modified by ion exchange to tailor it for use as a Trp nano-carrier. The developed nanocarrier was characterized by Fourier-transform infrared spectroscopy (FTIR), which demonstrated the successful incorporation of Trp into the LDH matrix. Subsequently, the release profiles of Trp were determined. The biological functionality of LDH-Trp was tested in a bioassay in Arabidopsis thaliana plant model system. The primary root growth of Arabidopsis seedlings is strongly inhibited by high concentrations of free Trp. Arabidopsis seedlings cultivated in LDH-Trp exhibited similar root growth than free Trp. Our findings suggest a promising scenario for employing LDH as a nanocarrier of Trp in the development of novel agro-inputs.

MOF-808 on Roundup® commercial glyphosate adsorption

Caroline Batistin da Cruz Almeida[1], Honério Coutinho de Jesus[1], Priscilla Paiva Luz[1]

[1]Universidade Federal do Espírito Santo (*Departamento de Química*)

e-mail: carolbatistin_@hotmail.com

Glyphosate (GLY) is an organophosphate herbicide, active compound of the commercial formulation Roundup® and hundreds of other agricultural pesticides, and is currently the most sold herbicide in the world.[1] Metal-organic frameworks (MOFs) have been investigatedfor adsorption of GLY due to their porosity and availability of active sites, highlighting in this application zirconium-based MOFs.[2] In this work, the performance and kinetics of adsorption of glyphosate from the dilution of Roundup®, by MOF-808, until then not investigated for this application, were investigated. This MOF was synthesized by two different routes, one in organic solvent (MOF-808-DMF) and the other in aqueous medium (MOF-808-H_2O). The Langmuir model showed a better fit to the adsorption isotherm obtained by both MOFs, reaching the maximum adsorption capacities (q_{max}) of 273.2 mg g^{-1} and 277.0 mg g^{-1} for MOF-808-DMF and MOF-808-H_2O, respectively. Although they have approximately the same qmax value, MOF-808-DMF has better kinetic performance compared to MOF-808-H_2O, adsorbing 70% of the GLY in solution in just 10 minutes. This performance is possibly associated with its smaller particle size (277,0 nm), which increases the availability of external adsorption sites compared to MOF-808-H_2O (596.5 nm), which are the first to be reached after the intrafilm diffusion of GLY. These results confirm the potential application of MOF-808 in the adsorption of GLY and demonstrate the importance of textural characteristics in the adsorption performance of MOF-type materials.

The indiscriminate use of fertilizers and pesticides has been linked to environmental pollution, the emergence of agricultural pathogens, and a loss of biodiversity. To address these issues, current efforts are focused on researching eco-friendly alternatives for protecting plants from stress. The aim of our project is to use nanoclays such as bentonite (Bent) and anionic clays such as layered double hydroxides (LDHs) to deliver active compounds such as Salicylic Acid (SA), a phytohormone that provides stress protection in plants. Previously, we used Bent as a delivery matrix for SA (Bent-SA), demonstrating that foliar application induces innate defense mechanisms in plants and provides protection against biotic stress [1]. However, the incorporation and sustained release of SA was not optimal in this matrix. Therefore, in this study, we aimed to use alternative matrices for delivery: LDHs (LDH-SA) and Bentonite previously functionalized with Chitosan (Ch), a polysaccharide with antimicrobial activity and plant growth-promoting properties (Bent-Ch-SA). The developed nanocomposites were characterized by Fourier-transform infrared spectroscopy (FTIR), demonstrating the incorporation of SA in both matrices used. Using UV-Vis spectroscopy, we determined the loading efficiency of SA and the in vitro release profiles in aqueous solutions. The results indicate that Bent-Ch-SA retains a maximum of 5,42 % of SA and releases a maximum of 13,5% after 30 extractions of the resuspension medium, while HDL-SA retains 16,4% and releases 40,1%. Western blot assays revealed that defense markers were accumulated at 48 h upon application in tomato seedlings. Our findings indicated that nanoclay systems are promising bioactive carriers to improve growth and stress protection in plants.

e-mail: heberandrada@hotmail.es

Developments in the area of nanotechnology have enabled important advances in the area of agriculture. In this regard, nanogels have very interesting properties, such as good biocompatibility, high porosity and high loading capacity for micronutrients used in agriculture. These nanogels can be prepared from a simple one-step method by heterogeneous polymerisation of monomers [1,2]. These nanogels have been observed to exhibit sustained release of micronutrients over time [3]. In this work, we evaluated the formation of nanogels based on polyetheramine (PPO) and bis-epoxide (BisE). An Fe salt was used as a micronutrient to load into the nanogels. The nanogels were physicochemically characterised by DLS, zeta potential (ZP), TEM, SEM and biological assays were performed to evaluate their cytotoxicity. It was observed by TEM and DLS that these nanogels have a size between 200 and 500 nm depending on their composition, and that the size increases as a function of the micronutrient concentration. The surface charge was measured by ZP. At basic pH, the nanogels show a negative surface charge and for pH below 7, their surface charge is neutral or slightly positive. During cytotoxicity tests, it was observed that the nanogels have high cell viability and are viable for use in agriculture.

The use of waste and the reduction of cement consumption is a growing demand in the civil construction industry [1]. This study aims at the production and characterization of mortars with glass powder as a partial substitute for cement and babassu coconut fiber (FT) as an additional reinforcement, in order to contribute in a sustainable way to a better disposal of this waste. The mixtures were prepared with a ratio of 1:3 cement/sand (in mass) and 0.7 water/cement. Cubic samples were prepared and named 0%/FT (0% glass powder and 0.5% FT) and 10%/FT (10% glass powder and 0.5% FT). By XRD (X-Ray Diffraction) the FT chemically treated with NaOH, showed an increase in crystallinity due to the removal of non-cellulosic (amorphous) components, which may contribute to better adherence of the fibers/mortar. FRX (X-ray Fluorescence) confirms the pozzolanic characteristic ($SiO_2+Al_2O_3+Fe_2O_3$ >50%) of the glass powder. For mortars, 0%/FT and 10%/FT, the mass consistency indices of respectively 27.3 ± 0.6 and 28.6 ± 0.3 cm were obtained. Thelow hydrophilic character, low FT content and absence of water absorption by the glasspowder, maintains the water/cement ratio effectively present in the mortar, so that the small variation between the results is influenced by the greater packing (density) of the 10%sample /FT. After 28 days, 0%/FT and 10%/FT showed compressive strength of 14.3 ± 0.5MPa and 13.3 ± 1.4 MPa, respectively, with no statistically significant difference. This can be attributed to the presence of fine glass particles, which, in addition to favoring mortar compaction, possibly had a good interaction with the FT/cement. Such results can contribute to the management of residual waste, reduction of cement and the reduction of the impact on the environment.

Chitosan (CS)-based materials have emerged as a promising alternative to replace toxic chemical compounds. These materials exert antibacterial activity (AbA) against phytopathogens [1]. The antibacterial properties of CS nano-microparticles (CS-NP/MP) depend on several intrinsic and extrinsic factors such as size and morphology of the CS- NP/MP, zeta potential (ZP), interacting pH, presence, and nature of functionalized compounds in the CS-NP/MP [2]. In this study, we describe the synthesis and physicochemical characterization of a set CS-NP/MP. Moreover, we evaluate the effect ofpH on the ZP of the CS-NP/MPs and its impact on their AbA. The particles were produced byionic gelation using tripolyphosphate (TPP) as a crosslinker, and during the synthesis process, different parameters were assayed (CS:TPP ratio, type, and agitation time). The obtained particles, designed as CS-NP, CS-MP1, and CS-MP2, exhibited similar sizes butcontrasting ZP values (13.9, 33.7, and 4.78 mV, respectively). Our results showed the ZP ofCS-NP/MP and its AbA against *Pseudomonas syringae*pv. *tomato*DC3000 decreases with increasing pH of the medium. Therefore, we describe an important role of pH to determinethe ZP of the materials and consequently the electrostatic interaction between the positivelycharged polymer and the negatively charged surface of the microorganism. We discuss ourfindings in light of the material properties and opportunities to use CS-NP/MP as a new typeof biomaterial in modern agriculture.

In face of the concerning population growth predictions, food security is one of the biggest challenges of the next decades. Better plant nutrition is pivotal to increase food production and could be achieved sustainably with the development of smart environmentally-friendly fertilizers. Phosphorus (P) is vital for crop yields, but the use of P fertilizers is often associated with eutrophication of freshwater systems. To address this issue, fertilizer design plays a critical role. Sulfur(S) is also essential to plant metabolism, often managed with elemental sulfur (S8) application as a matrix to carry other fertilizers. Nevertheless, S8 matrices tend to be brittle and non-uniform, and the recovery of S8-S by crops depends on its biological oxidation to sulfate, which is significantly slow. Polysulfides (PolyS) are S-rich materials recently studied by our group as multifunctional S-fertilizers with superior S oxidation. In the present work PolyS was investigated as a matrix for the fine dispersion of P sources, forming controlled-release fertilizer (CRF) composites with enhanced phosphate and sulfate delivery PolyS is an ideal substitute to conventional CRF polymers, being an easily processible and malleable material with an agronomic role as a S fertilizer. The polymer was obtained with the inverse vulcanization of S8in the presence of an alkene (i.e.: soybean oil), a green one-pot method with no solvent use and great atom economy. The polymerization of S8crystalline structure produces an amorphous material with less ordered S-chains, proposed to favor the conversion to sulfate. Results showed that the matrix favored P dissolution while also preventing a fast release, therefore promoting an ongoing P-delivery. Moreover, soybean cultivation with the composites achieved higher S use efficiency, plant biomass, and root proliferation than with a commercial reference, proving PolyS potential as a versatile and efficient matrix for sustainable P and S fertilization. e-mail: felipeb.alves@hotmail.com

The use of polymeric materials in agriculture and horticulture has seen a significant increase in recent years. Not only are they replacing traditional materials, but they are also providing a significant improvement in the technology used in the cultivation of crops and vegetables, the construction of storage for crops and animals, and in the equipment and drainage technologies used in agriculture.[1] Herein, a one-step preparation of polymeric gels was demonstrated by "click" characteristics of amine-epoxide reaction. The hydrogels, known as poly (amino alcohol ethers), was obtained via ring opening of epoxide group through the reaction of a polyetheramine (PPO) and poly (ethylene glycol) diglycidyl ether (PDE). The influence of molar ratio of PPO:PDE was evaluated. The final materials were characterized by DLS, SEM, thermal analysis (TGA). The cytotoxicity of the materials was evaluated by XTT assays. The hydrogels were biocompatible and the size of the particles can be fine tuning by the synthesis conditions. Seed germination (using corn seed as model) was evaluated using polymeric nanogels with Zn ions embedded. The preliminary result, demonstrate that structured gels could be used as novel technology for enhance seed germination and open an avenue of possibilities to be used as foliar applications for plant nutrition.

The final disposal of natural adsorbents saturated with pollutants creates a major problem, as it is not always possible to treat or reuse such materials, resulting only in the transfer of pollutants from a fluid phase to a solid phase. [1]. In view of this, this work aimed to evaluate the production of biochar from kapok pods as a destination for this material, which was previously used as an adsorbent for the removal of rhodamine B (RhB) dye. The production of biochar was carried out by the hydrothermal method followed by thermal activation, using 5 g of the saturated kapok capsule. Two applications for hydrochar (HC) asa destination were evaluated: its use as an adsorbent also for RhB, and its direct disposal asa soil conditioner. Through the analysis of the pH of zero charge, it was observed that the neutrality region of the HC occurs at pH 6. Affinity and pH influence tests were carried out, using RhB at 10 ppm and 0.1 g of HC as adsorbent, verifying excellent adsorptive power of the produced material, reaching removal superior to 92% in the different applied pH ranges, such performance being superior to the natural material in the same conditions. Being a promising alternative for the treatment of concentrated natural adsorbents. Tests of application of the material as a soil conditioner were carried out using a variation of 4 to 10% of HC in the soil composition and it was observed that the material did not present any deleterious effect, since the seedlings presented satisfactory development in all samples, with growth greater than 60 cm in shoot length, 41 cm of radicle and 4 leaf units, in all cases studied. Both destinations for HC being excellent alternatives.

e-mail: kathylen.santos@icf.ufal.br

The development of biodegradable materials is seen as an alternative in reducing environmental damage caused by the disposal of products based mainly on synthetic polymers. Aiming at this, chitosan is a polysaccharide with physicochemical characteristics and biocompatible with biological systems, having potential for the development of carriers of bioactive substances. With this in mind, the present work aimed to obtain and characterize hybrid polymeric films containing açaí (Euterpe oleracea) extracts. The films were produced by the casting method (mixture of chitosan, cationic mineral clay, polyethylene glycol and açaí), using the açai pulp aqueous extract and the acidified aqueous extract. The films obtained were characterized by SEM, FTIR, microbiological and antioxidant (DPPH) activity techniques. The SEM showed films with a surface of compact appearance, with cracks and small structures similar to holes. The FTIR analyses bring information of interactions between the polymer and clay, also revealing possible intercalations of phenolic compounds inside the hybrid film. The minimum inhibitory concentration (MIC) evaluation showed inhibition efficiency in both types of extract, highlighting a better activity in the acidified extract for the four strains evaluated. The microbiology through disc diffusion technique showed similar results in relation to the acidified extract. The results for the antioxidant capacity reveal that the acidified açaí extract presented capacity to inhibit the free radical, as well as the films, showing that afterthe polymerization process, to obtain the hybrid films, the biological properties of the extracts were maintained. The set of results presented reveals very effective and promisingfilms for future use of these systems in wound treatment.

Abstract

According to FAO and CMA, in 2050 the world population will reach more than 9 billion people and to meet this growing and increasingly demanding demand for food, it will be necessary to increase food production by at least 60%. In this way, innovation will be crucial for sustainable food production, that is, without soil degradation and water waste [1-2]. The increase in agricultural production, without innovative solutions for replenishing nutrients in the soil and reducing water consumption, inevitably results in soil depletion and evaporation of up to 50% of the water intended for irrigation. To reduce soil depletion and at the same time increase agricultural production, preserving thousands of hectares of forests and native forests, as well as fauna and flora, a large amount of fertilizers are currently used. Thus, the objective of this work was to synthe polyvinyl alcohol (PVA) and ethylenediaminetetraacetic dianhydride (EDTAD) hydrogels, characterize them through FTIR, SEM and biodegradation analysis, in addition to evaluating their kinetics of absorption and release of water and NPK nutrients , through UV-VIS and flame photometry techniques. Through the analyzes carried out by FTIR, it was verified that the hydrogel was successfully synthed, observing the expressive increase of the free OH band at 1320 cm-1, the bands present at 1809 cm-1 and 1755 cm-1 referring to the anhydride of The carboxylic acid present in EDTAD is non-existent in hydrogels due to ring opening for intermolecular hydrogen bonding, which results in cross-linking of the chains. The kinetics of absorption and release of NPK was built, through which the feasibility of applying the hydrogel to release NPK and rational use of water was proven.

Glycerol is being investigated as an alternative and environmentally friendly feedstock for polymer synthesis. As a trifunctional alcohol, its use in polycondensation reactions is particularly appealing [1]. Polyglycerol Citrate can be formed when citric acid and glycerol react (PGCit). Because both monomers are biodegradable and nontoxic, their management is dictated by ecology and green chemistry principles, and the synthesis can be done by polycondensation with water as the only by-product [2]. Furthermore, despite numerous studies demonstrating the ability of beneficial microorganisms to increase plant development, few bioinoculants adhered to seeds are commercially available because maintaining viable microorganisms during seed treatment and storage is a major problem [3]. To address this issue, the current study suggests using PGCit as a new type of inoculant vehicle for coating soybean seeds with ***Bradyrhizobium***. Furthermore, PGCit can be solubilized in liquid inoculant formulations, making seed application simple for farmers. The ^{1}H NMR results confirmed that it could be made in a simple one-pot polycondensation yielded in the PGCit structure, with some water solubility as desired. ***Bradyrhizobium***survival was increased by seed coating with PGCit on seeds stored for more than 14 days, resulting in successful bacterial and plant colonization. Greenhouse studies have confirmed their beneficial effect on soybean, while the polymer coating protects bacteria and seeds from abiotic stress in the environment and promotes successful inoculant colonization based on the number of nodules counted after harvesting the soy plants. As a result, the polymer proposed showed to be a promising eco-friendly approach to improving soybean production via the use of a microbial inoculant.

Insect pests cause great economic losses to Brazilian agricultural plantations [1]. Thus, producers excessively use insecticides to avoid damage to the production chain[1]. R. palmarum is the most important pest of coconut cultivation, as studies on these insects have been carried out for decades on the invasion and destruction of plantations [1]. Currently, plastic sachets and Eppendorf polyethylene tubes are used as rhynchophorol releasers, potent aggregation pheromone[2]. The objective was to study the thermal degradation of microspheres containing rhynchophorol with sodium alginate by extrusion. The characterization of the microspheres was performed by thermal analyses, Thermogravimetry (TG), and Differential Scanning Calorimetry (DSC). According to the TG analyses, for treatment H, the mass loss was 19.152% from 26.02 to 215.90 ºC, in the first moment, and after, the mass loss of 52.486% from 215.90 to 531 .53°C. As for the DSC results, there was a slight exothermic event, around 132 °C, and a very sharp peak for an exothermic event around 485 °C. These data mean, respectively, the loss of volatile compounds and the decomposition of alginate and rhynchophorol. It is worth mentioning that the formation of microspheres of the rhynchophorol pheromone by the extrusion technique with sodium alginate and calcium chloride has not yet been reported in the literature, which demonstrates the originality of this work.

U-Sustainable Production of Nanomaterials and Ink Formulations for Affordable, Efficient, and Reusable Printed Electronics

Additive manufacturing of batteries: Comparison between fabrication processes

Sergio Pinilla[1,2], Sean Ryan[1], Lorcan McKeon[1], Meiying Liang[1], Ahin Roy[3,1], Sebastien Vaesen[1], Valeria Nicolosi[1]

[1]Trinity College University of Dublin, [2]IMDEA Energy, [3]Indian Institute of Technology Kharagpur

e-mail: sergio.pinilla@imdea.org

At the moment, emerging applications and devices such as biomedical sensors or micro-electro-mechanical systems, are limited in shape, size and price by the energy storage devices that power them. In this regard, printing technologies propose an affordable and adaptable alternative of creating complex architectures that could maximize the energy density of batteries and supercapacitors[1]. Although a substantial effort has been done to push forward the application of printing strategies for energy storage devices, this field is still in its infancy and a lot of challenges remain[2]. A recurrent problem in this field is the lack of information on how the micro-structure of the composites is affected by the fabrication method and how this impacts the performance of the final device.

In this work, we present a systematic study of the changes in the electrode materials when we move from traditional techniques to printing-based methods. We use ink-based techniques encompassing traditional battery fabrication methods such as slurry casting and filtration and more advanced ones such as extrusion printing, spray coating and aerosol jet printing. The methodology used for the electrochemical analysis was mainly the analysis of the capacity-rate curves, that were fitted to physical models[3]. The differences between deposition techniques were correlated to the observations made by morphological and structural-based techniques, such as TEM, SEM and BET.

It was found that the deposition technique changes the conductive network arrangement, creating segregated[4] or randomly arranged networks. It was also found that porosity and out-of-plane conductivity are other factors that can be massively affected by the fabrication technique and its effect on the electrochemical performance is very significant.

Evaluation the environmental impact of electronics and how printed electronics can improve sustainability

Jeff Kettle[1]

[1]University of Glasgow

e-mail: jeff.kettle@gla.ac.uk

For more than 50 years, advances in electronics have revolutionized all socioeconomic sectors. However, in pursuit of this goal, the industry has evolved whereby the materials and manufacturing processes are decided by the technical and economic requirements, and not sustainability, resulting in poor practices and unintended outcomes. This presentation will first review some of the drivers and opportunities for sustainable PCB manufacturing, and then target specific areas of processing to induces changes that could improve the sustainability of electronic assemblies. Process modelling has been undertaken, and environmental assessment conducted, to support the final recommendation to improve the sustainability of the product. As such, a life-cycle assessment (LCA) was performed on a simple Printed Circuit Boards (PCB) made using the traditional manufacturing approach with FR-4, polyimide and paper-based substrates and this can be used to review the environmental impact at each key stage of the life cycle. The scope was cradle to grave, including embodied impacts, transportation, energy used during manufacturing, waste material generated and disposal. The impact of different processing steps was considered, all scored using the ReCiPe Endpoint. Results show that consideration should be given to PCB design, including number of layers used in multilayer boards. We also report on how solder and die attach material has a choice has an impact upon environmental profile. Generally, we find lower temperature solders and die attach materials lead to improve environmental impacts as less electricity is used, coupled with the small volumes of attach materials used. Finally, we show the move towards additive manufacturing and the use of alternative material and processes can reduce the environmental impact of electronic products which is validated through Life Cycle Assessment (LCA) calculations.

Sustainable Devices: From Ink Formulation to Their Printability

João Coelho[1,2] and Emanuel Carlos[1]

The advent of portable electronics has undoubtedly brought convenience and value to our lives. However, the decreasing lifespan of these devices has led to increased pressure on e-waste management. Therefore, it has become imperative that future electronic devices should be designed based on sustainable principles to mitigate this issue[1–3]. The use of additive manufacturing techniques, particularly printing techniques, and the development of nanomaterials can lead to the creation of low-waste and eco-friendly products. Additionally, device implementation in eco-friendly substrates, such as paper and other cellulosic materials, further promotes the sustainability of modern industrial production methods.

In our research, we have provided a comprehensive analysis of the advancements made in the development of nanomaterial inks and their application in the printing of electronic components. Specifically, we have discussed the creation of ink formulations for metal oxides and low-dimensional materials that are both cost-effective and sustainable. Our focus has been on two main approaches: solution combustion synthesis (SCS) and liquid phase exfoliation (LPE)[4,5]. We have noticed a correlation between ink properties, such as viscosity, material concentration, and the physic-chemical properties of active materials, with their printing capabilities. Therefore, it was necessary to adjust the rheology of the inks to achieve functional printed devices. In this talk, we discuss the printing techniques and the printability of functional inks, along with the challenges associated with them. Finally, we have provided an outlook on the future of sustainable printed electronic applications.

Bio-sourced Nanomaterials and Solvents for Electronics and Energy Applications

Carla Cristina Decandio[1], Monica Jung de Andrade[2]

[1]Merck S.A., [2]Millipore Sigma

e-mail: carla.decandio@merckgroup.com

A global effort is being made towards the sustainable development of electronics and energy applications. A careful choice of materials can significantly reduce the environmental impact of each main component of electronic/energy devices. Environmental and human health impact of e-waste derived from consumerism requires a mindset change from linear to circular thinking. Similarly, whilst clean energy has been a focus for several governmental initiatives, many of such more sustainable devices for energy harvesting/storage still require working with toxic or critical chemicals [1]. In this context, Merck KGaA brought several solutions for the workflow development of electronics and clean energy devices. Among such, we will cover ourbio-sourced customized solvents for electronics/energy applications, our bio-sourced nanomaterials, and our R&D100 awarded inks for more sustainable manufacturing [2]. We will describe how these more sustainable solutions do not compromise the reliable performance of your device. For instance, our bio-sourced high surface area (1155 ± 69 m2 /g) single laye sheets graphene for battery has an extremely high pore volume (1.7 ± 0.22 cm3 /g), enabling maximum energy power and density, as wellas fast charging and no degradation over thousands of cycles. The capacity of our anodeafter charging at 10 C (minutes) is similar to graphite capacity at a charge rate of 0.1 C (i.e.10 hours charging time). It can charge in a few minutes instead of hours and showed a 5-fold increase in capacity at 0.1C vs. graphite anode (standard).

The production and accumulation of electronic waste have become a significant problem, as most electronic devices use non-degradable materials. Therefore, sustainable fabrication methods and biodegradable materials are required to mitigate this problem. Laser-induced graphene (LIG) is a sustainable way to produce high-quality porous graphene electrodes that do not require the use of toxic reagents. Furthermore, LIG can be produced from organic, biodegradable substrates such as cork, cotton, and paper. Due to its high conductivity, flexibility, and porosity, LIG has been successfully employed as electrodes for biosensing and energy storage, namely supercapacitors Recently, flexible supercapacitors have attracted attention for applications as efficient power source in wearable electronics. In this work, we present the sustainable fabrication of supercapacitors using paper-basedLIG electrodes with electrodeposited manganese oxide (MnO). We produced the LIG by irradiating with CO_2laser a piece of Whatman paper grade 1 treated with a fire retardant. We deposited the MnO on LIG in a three-electrode cell using manganese acetate as a precursor (0.1 M). We fabricated a symmetrical supercapacitor using Whatman paper grade4 soaked in PVA/LiCl as the separator. XPS analysis indicated three oxidation states for theMn: possibly MnO, MnO_2, and Mn_2O_3. From galvanostatic charge/discharge curves, we obtained a maximum areal capacitance of 86.9 mF cm^{-2}(at 0.1 mA cm^{-2}). Moreover, the device presented a remarkably high areal energy of 7.3 μWh cm^{-2}. In summary, we produced supercapacitors using sustainable techniques and materials that are competitive with devices produced by conventional pollutant methods.

e-mail: rogermimorais@gmail.com

The huge amount of electronic waste brings the need for sustainable electronic devices aiming to reduce environmental damage. This, coupled with the rise of the Internet of Things (IoT) creates a niche for a biodegradable printed electronic. For instance, it can be envisioned smart package with printed electronic circuits that allow monitoring of the product' s conditions exposure and states its quality. The main challenges in making this idea a commercial reality are the development of transistors and conductive tracks printed directly into the packages materials, as the paper. Laser-Induced Graphene (LIG) is an easy technique that stands up to produce graphene. Electrolyte-gated transistors (EGTs) offer high sensitivity, low voltage and power usage, making them perfect for flexible devices. LIG and EGTs show promise for flexible printed electronics and combining them is crucial for progress. Our study integrates LIG and EGTs, demonstrating their potential for flexible printed electronics. We use LIG to produce conductive tracks in kraft paper without any treatment and to produce transistor electrodes (gate, source, and drain). The tracks conductivity depends on LIG parameter as scan velocity and laser power. We achieved a conductivity of ~50 Ohms/sq, which is suitable for use as EGT electrodes and as track connectors. This work is shown EGTs on Kraft paper and in polyamide substrates using ZnO nanoparticles and PEDOT/PSS as active material. The electrode was produced in situ by LIG, the semiconductor was deposited by spray and the electrolyte was honey, dispensed by hand. We found the Ion/Ioff ratio of 103 and Ion on the order of 0.5 mA for the transistor in polyamide. Although in the paper the results are modest, they also show suitable for several applications. Also included pulsed characterization showing the neuromorphic application potential. This work shows the viability of producing printed EGTs on paper using LIG tracks and electrodes.

Piezoresistive ABS/CNTs Nanostructured 3D Printed Sensor for Industry 4.0

Luciano José Barbosa Quaresma[1,2], Rosielem Silva Dias[2], Dhonata Sebastião Caldas Oliveira[1,2], Kelly Costa Alves[1,2], Marcos Allan Leite dos Reis[3,2], Waldeci Paraguassu[1]

e-mail: luciano.quaresm@gmail.com

The advent of Industry 4.0 based smart factories has resulted in a growing demand for intelligent sensors to enable the integration of cyber-physical systems across their production chains. This, in turn, facilitates the real-time automation and optimization of their processes [1]. Carbon nanotubes (CNTs) based nanocomposites are suitable for sensors, because of the processability of the matrixes and the properties of the CNTs [2]. Inthis sense, the present study developed a low-cost, nanostructured poly(acrylonitrile- butadiene-styrene) (ABS) smart sensor produced by additive manufacturing. After printing the samples by fused deposition modeling (FDM), a solution layer of acetone, dimethylformamide and CNTs functionalized with carboxylic acid was applied using an aerograph. Electrical measurements made with a model 6487 Keithley picoammeter after solvents' evaporation showed the electrical resistance drop from 1012 to 103 Ω after five layers of the solution. Furthermore, the samples behaved as a piezoresistive metamaterial, since their electrical resistance changed around 1 kΩ with physical deformations due to pressures of up to 0.27 MPa. Field Emission Gun Scanning Electron Microscopy (FEG-SEM) showed the nanostructured film spreading after each layer of CNTs as well as the interaction between the ABS substrate and the nanotubes. Raman spectroscopy also showed this interaction, as seen by the presence of characteristic bands of both on the nanocomposite Raman spectra. These results show the electromechanical response of the material, giving possibility to implement it with ESP32 microcontroller as smart sensor for IoT applications.

The field of materials science has seen significant advancements in the production and characterization of graphene-based hybrid inks. These inks are created by combining graphene with other materials, such as polymers or metals, to produce new materials with unique properties. The current paper proposes a method for producing hybrid graphene ink combined with copper and silver. The process involves synthesis, deposition, and characterization. Firstly, graphene oxide was synthed using the Hummers method. Then three main versions of the ink were prepared, including a control version without metals, a version with a low concentration of silver, and a version with a low concentration of copper. The material was then deposited onto microscope slides using the doctor blade coating method. The resulting samples were analyzed using various techniques, including light microscopy and mechanical profilometry to check for topography, homogeneity, thickness, and roughness. In addition, raman microscopy, X-ray diffraction, and infrared microscopy were used to verify crystalline quality and chemical structure. Otherwise, conductivity measurements were performed using the 4-probe and Arduino systems. Additionally, uv-visible light spectrophotometry, viscosimetry, and optical profilometry were used to investigate the inks optical properties. Scanning Electron Microscopy (SEM) and viscosimeter analyses were also performed for the analysis of additional properties such as viscosity and stability of the inks produced. The samples showed a homogeneous appearance, low defect density, thermal stability, and high conductivity, making them suitable for use in electronics, energy, and biomedicine.

A Study of a Hybrid Schottky Photodiode Based on ZnO/AuNPs and PEDOT: PSS to Enhance UVA Detection Through Plasmonic Effects

Luis Henrique Tigre Bertoldo[1], Gabriel Leonardo Nogueira[2], Douglas Henrique Vieira[1], Neri Alves[1]

[1]Universidade Estadual Paulista "Júlio de Mesquita Filho" - Faculdade de Ciências e Tecnologia - Campus de Presidente Prudente (*Física*) , [2]Universidade Estadual Paulista (***Departamento de Física e Meteorologia***)

e-mail: luishenrique198@live.com

ZnO is an n-type semiconductor with a direct bandgap of ~3.3 eV, making it an excellent candidate for application in UVA photodetectors. Furthermore, the insertion of gold nanoparticles (AuNPs) into the ZnO bulk can broaden its absorption spectrum by plasmon-induced charge separation (PICS). The Schottky diode (SD) based on the ZnO/PEDOT:PSS rectifying junction is an excellent alternative among several photodetector devices. Here, we investigated the effects of adding AuNPs into the ZnO bulk on the performance of a SD for application as a photodetector. Numerical simulations using the finite element method were employed to evaluate the SD's behavior based on ZnO/AuNPs in both dark and UV-illuminated conditions. For the experimental work, the devices were fabricated as follows: i) Al (~15 nm) was evaporated as the bottom electrode, followed by the deposition of ~80nm of ZnO via spray pyrolysi ii) incorporation of AuNPs-like structures by the deposition of Au (~1 nm) to form unconnected gold spot iii) spray deposition of additional ~20 nm of ZnO over the AuNP-like structure; iv) deposition of the PEDOT:PSS as the top electrode through spray coating. The morphological and optical characteristics of the ZnO semiconductor films, with and without the AuNPs within its bulk, were analyzed using UV-VIS, AFM, SEM-FEG, and others. The electrical characterization of the SD was carried out through DC and AC measurements. The I-V curve showed a rectification of 3 orders of magnitude in the dark, while the rectification practically disappeared under UV illumination. The AC measurement in C-V mode showed an improvement under UV light due to the presence of AuNPs. In summary, we confirmed enhancements of detection through the plasmon effect by incorporating AuNPs in the ZnO bulk. This study can potentially expand the scope of Schottky diode applications as a photodetector.

The search for technological advances in recent years has attracted research into semiconductor materials, in which they have a fundamental role in electronics, due to their importance for the production of devices and sensors in the solid state. This work seeks to study the characterization and optimization of the preparation of thin film zinc oxide films obtained by the Sputtering Physical Vapor Deposition (PVD) technique, aiming to control its semiconductor behavior, as well as the fabrication of two-terminal devices by deposition of electrical contacts on the films. The characteristics of the electrical contacts in ZnO, whether ohmic or Schottky, depend not only on the conductors used, but also on the characteristics of the ZnO film itself, such as the doping density. In this study, the morphological characterization of the ZnO film will be carried out using X-ray diffraction analysis (DRX), scanning electron microscopy (SEM), X-ray fluorescence (FRX), UV-Vis, in addition to electrical characterizations of the two terminals as a diode depending on the electrical contacts. The electrical characterization will be studied using biodegradable electrodes such as molybdenum (Mo) and zinc (Zn) in order to develop a basic study for the development of biodegradable devices based on ZnO.

Nanotechnology has been widely disseminated, with nanoparticles (NPs) used for several applications, from medicine to energy. Metallic NPs have attracted great interest and have a wide range of applications, mainly to their unique features, such as characteristic absorption linked to the shape and composition of the nanoparticles. An example is silver nanoparticles (AgNPs) that present absorption around 400 and 500-700 nm for nanospheres and nanoprisms, respectively. They feature a small size, large surface area, low toxicity, low cost, and may provide a more environment-friendly nanomaterial.[1] Commonly, the synthesis of AgNPs uses materials that can generate toxic by-products, such as sodium borohydride, used as a reducing agent. The development of more sustainable synthesis is one aspect that emerges from the philosophy of Green Chemistry. This area provides discussions, criteria, and parameters to generate new theoretical and experimental knowledge in chemistry [2]. In this line of reasoning, one method that emerges to contribute to a greener synthesis is mechanochemistry. It presents a greener, more efficient, and innovative possibility to promote solvent-free syntheses through the supply of mechanical energy [3]. Thus, this work aims to synthesize AgNPs via mechanochemistry, free of solvents and toxic additives. Nanoparticles were prepared under grinding for 30 minutes at a frequency 25Hz and analyzed via UV-VIS spectroscopy and TEM. The results showed that AgNPs, with different stabilizers, were successfully obtained. Thus, mechanochemistry presents the potential to develop greener and unconventional methods to prepare nanomaterials.

e-mail: mayk.nascimento@unesp.br

The printed electronic has shown excellent potential for developing sensors that can be incorporated into personal adornment, cards and package. Zinc oxide (ZnO) films, obtained from organic precursor solution or by printing nanoparticle dispersion, have been widely studied for their ability to sense ultraviolet radiation (UV), gases and vapors. The interaction of ZnO films with the molecules present in the air causes them to modify their electrical conductivity. This phenomenon is mainly caused by the adsorption and desorption of oxygen and water species on their surface. When UVA is incident on ZnO films in an atmosphere with controlled humidity, it is possible to investigate how humidity modifies the transport mechanism in a device. In this work, we present the fabrication and characterization of photodiodes based on a sprayed ZnO active layer in which the persistent conductivity effect related to humidity is studied. All measurements were conducted in an environment with controlled relative humidity (RH). The photodiode architecture used bottom aluminum electrodes and PEDOT:PSS as the top electrode, sandwiching the ZnO layer. After UV incidence (355 nm), the device underwent Current x Voltage measurements at different humidities. The obtained curves were used to extract the differential slopes (m), revealing an ohmic conduction behavior (m=1) at low RH, and the same device transitioned to a space-charge limited current (SCLC) behavior as the RH increased. These findings demonstrate that exposure to moisture induces changes in the conduction mechanism of ZnO, making it a promising candidate for gas sensing applications given the linearity of the parameters observed.

Printing techniques offer a cost-effective way to fabricate electronic devices. Despite the challenges such as limited lifetime, poor resolution and inferior performance, printed electronics have gained prominence in niches such as printed sensors. ZnO is a versatile semiconductor for printed UV sensors due to its printability by various techniques such as inkjet and spray-coating. ZnO also presents biodegradability and low toxicity. Here, we propose a spray deposited ZnO junction with a biodegradable cellulose-based electrolyte ina metal-insulator-semiconductor (MIS) structured device using ITO electrodes, aiming capacitive photodetectors and phototransistor applications. By using impedance spectroscopy, we investigated how UV exposure changes the device's interfacial properties, evaluating the information on interface trap states, flat-band conditions and carrier concentrations. The capacitance-frequency curve displayed a plateau at low frequencies under zero bias due to the formation of electric double layer at the ZnO/electrolyte interface. With the voltage increase, the device was driven to the accumulation regime, increasing the capacitance to 0.3 µF at V=1V. Also, the dielectric loss starts to show two dielectric relaxation peaks, and a changed plateau shape. The extra peak can be attributed to artifacts such as edge leakage due to geometric factors and parasitic capacitances. A carrier concentration of $2.5\times10^{19}\text{cm}^{-3}$was estimated from a capacitance-voltage curve in the dark, which was increased to $7.3\times10^{21}\text{cm}^{-3}$during a 355nm UV exposure. C_{UV}/C_{dark}-voltage plot presented a maximum of ~50 at V≈0.2V. Finally, the MIS structure was applied as a phototransistor, and its dark and under-UV transfer characteristics presented a correlation with the MIS capacitor analysis. Our findings indicate that the proposed MIS-structured devices can be a promising approach for UV sensing applications.

e-mail: leandrojosesena@gmail.com

Temperature sensors make up nearly 80% of the global sensor market and offer great potential for improving both conventional materials and developing new materials such as nanocomposites based on carbon nanotubes (CNTs), as these materials possess intrinsic physical properties that enable the portability and rapid response of temperature sensing devices [1]. In this sense, this study describes a based on CNTs sensor and created through additive manufacturing by the process of Fused Deposition Modeling. For this, two serpentine-shaped samples (dimensions: 20 × 30 mm) were 3D printed using poly-lactic acid (PLA), and one of them was coated with a paint made from multiwalled CNTs functionalized with carboxylic acid, acetone, and dimethylformamide using an airbrush. After applying eight layers of paint, scanning electron microscopy micrographs revealed a randomly dispersed CNTs layer over the PLA polymeric matrix. This interaction was also confirmedvia Raman spectroscopy, as the PLA@CNTs sample showed characteristic bands from bothmaterials. Two-point measurements were made using a model 6487 Keithley picoammetershowed an electrical resistance drop from 145 GΩ (only with PLA sensor) to approximately730 kΩ (PLA@CNTs sensor). Additionally, a thermoresistance test via two-point measurement using heating/cooling cycles demonstrated a reduction/increase in the electrical resistance of the PLA@CNTs sensor and its response (based on the variation of the relative change in electrical resistance) was −4.75 ± 0.66 % when varying the temperature from 35 to 45 °C, characterizing it as a thermoresistive sensor. Therefore, this device can be suitable for applications in IoT (Internet of Things) for monitoring of human body temperature in real time.

e-mail: joseserbena@ufpr.br

Honey is a natural product produced by bees and has had an increasing impact on the economy. In general, Brazil has one of the largest production capacities of organic honey in the world, whose differential is the low contamination by pesticides and antibiotic residues, since the production is predominantly from native vegetation. However, this product is not free from food frauds that target illegal and often toxic adulterations of the product in search of increases in marketing profits, with an estimated 13% of honey samples in Brazil added with sugar syrup. Thus, it is of great interest to develop a sensor, cheap, easy to handle and interpret results, capable of detecting possible adulterations in honey in the apiary or meliponary itself through simple electrical measurements. In this work, progress towards the development of such a sensor based on electrolyte-gated transistors (EGTs) is reported, where a pure honey sample or a pure molasses sample is used as the liquid dielectric layer, placed between the gate electrode and the semiconductor channel. Transistors operations are validated and typical parameters, such as threshold voltage, on/off ratio, among others, are obtained. Two types of semiconductors are being investigated as channel, seeking for the best operating device's performance: (i) n-type zinc oxide (ZnO) thin films and (ii) p-type conjugated polymer poly(3-hexylthiophene-2,5-diyl) (P3HT), which increases the prospects of development of such a sensor.

e-mail: rogermirandamorais@hotmail.com

The production of flexible heating devices is an area undergoing constant evolution, with applications ranging from the textile industry to medicine. However, producing flexible electrodes with good heating properties and mechanical resistance presents a scientific and technological challenge. Graphene, a highly conductive and mechanically resistant material, has emerged as a promising choice for such applications. Laser-induced graphene (LIG), an easy form of graphene production using a laser to carbonize a hydrocarbon layer such as polyimide, has gained popularity. LIG can be applied to various substrates, including paper, which is cheap and biodegradable. However, most conventional techniques for producing LIG on paper require toxic and/or expensive chemical treatments, conflicting with its primary advantage. The use of untreated paper as a substrate is an affordable and safe alternative to produce graphene electrodes. In this study, we present the production of flexible electrodes using untreated paper as a substrate and their application in flexible heaters. Grid-shaped LIG electrodes were embedded in Kraft paper to manufacture heating devices. These devices can heat up to 30°C above ambient temperature in approximately 180 seconds under an applied voltage of 10V. We provide a comprehensive characterization of power and efficiency, considering the design layout and parameters used in the formation of LIG electrodes. The results show that flexible graphene electrodes using kraft paper as a substrate can be produced with excellent performance. Additionally, the produced heaters exhibit good mechanical resistance, making them a viable option for various sector applications. In conclusion, we present a new approach to producing resistant flexible heaters using graphene electrodes produced via LIG and untreated kraft paper as a substrate. This approach presents promising results and opens new possibilities to produce flexible heating devices safely and economically.

Thin Flexible Films Obtained by Slot Die Coating ofWater Based P3HT and P3HT:PCBM Nanoparticles

Júlia Ketzer Majewski[1], Maiara de Jesus Bassi Gobara[2], Lucimara Stolz Roman[3]

[1]Universidade Federal do Paraná (*Física*) , [2]Universidade Federal do Paraná, [3]Universidade Federal do Paraná (*Physics*)

e-mail: Julia_k.m@hotmail.com

With the slot die deposition technique it is possible to make much larger active areas than the spin coating technique with different substrates, allowing printing conductive inks in a similar way to a roll-to-roll printer inside laboratories and industries. Another feature that interferes with nanostructured devices scalability is the organic solvents for polymer inks that are highly toxic and harmful to the environment. In this way, the main goal of this study was the production of donor and acceptor nanoparticles in a stable suspension in water, which is a non-toxic and not harmful to the environment solvent, synthed by miniemulsion technique, obtaining an adequate dispersion for film depositions. We produced films for optical, chemical, morphological and electric characterizations, by slot die coating for a greater study of its properties. Besides that, slot-die films both in glass and acetate substrates were made for comparing the possibilities of transferring the technique to other types of flexible substrates. Measures for comparing the lifetime of the nanostructured and simple polymer based inks were also made. With the optical characterization it was possible to see the quenching between the donor and the blended nanoparticles of P3HT:PCBM, showing that there was a charge transfer between the donor and acceptor materials inside the nanostructure. The Raman spectrum of the P3HT and P3HT:PCBM nanoparticles showed that the chemical structure of the materials was not affected during the productionof the nanoparticles. The morphological study showed that the slot die coating printing methodology successfully produced an homogeneous film of the smaller nanoparticles withdiameters of approximately 30 nm.

V-Advanced nanocomposites for photonics : materials synthesis, optical properties and applications

Active aerosols to control the propagation of light

Jake Fontana[1]

[1]U.S. Naval Research Laboratory (*Optical Sciences Division*)

e-mail: jake.fontana@nrl.navy.mil

This work connects the fields of active plasmonics and aerosols to establish an active aerosol. We report the experimental dynamics and control of ensembles of gold nanorods suspended in air by varying the magnitude and frequency of externally applied electric fields, thereby demonstrating an active aerosol. We further show light filter, valve and gradient-index responses, demonstrating active aerosols as a novel type of optical element we define as component-less optics.

Characterization of Novel Nonlinear Optical Materials

Sanaz Faryadras[1], Eric W Van Stryland[1], David J Hagan[1]

[1]University of Central Florida (*CREOL*)

e-mail: s.faryadras@knights.ucf.edu

Many materials, especially composites can exhibit nonlinear refraction (NLR) and absorption (NLA) that exhibit complex temporal dynamics. As a result, measurements made for one laser pulse width may not accurately predict behavior with different pulse widths. One solution is to make measurements with multiple pulse widths, but a better solution is to use excite-probe techniques. Our group has developed a method, Nonlinear Beam Deflection, (BD) that allows sensitive time-resolved measurement of both nonlinear refraction (NLR) and absorption (NLA). The measurement uses an excitation beam to create an index gradient in the nonlinear sample, which deflects a probe beam, ant the deflection is measured using a quad-cell detector in the far field. It has been shown that the method hasa sensitivity to induced phase changes as small as 1/24,000 of a wavelength. By changingthe relative polarization of the excitation and probe, we can also separate the bound- electronic responses from slower and different-symmetry nuclear contributions. In gases and liquids where reorientational nonlinearities are important, and measurements at the magic polarization angle allow isolation of the ultrafast nonlinearities. This method also allows for measurements of nonlinearities using very different wavelengths for the excitation and probe. We have used this method to characterize the impulse response function for third-order nonlinearities in many materials and has been the primary methodused to measure the properties of transparent conducting oxides. This allows accurateprediction of the nonlinear refraction and any pulse width longer than that used for the BDcharacterization. The method proves to be very useful in organic materials and nanocomposites that may show strong nonlinear absorption, as compared to other methods, such as Z-scan. We will show some new results that demonstrate how to maximize sensitivity via geometric optimization.

Earth-Abundant Layered Materials: VibrationalProperties and Nanophotonics Applications

Ingrid David Barcelos[1]

[1]Brazilian Center for Research in Energy and Materials (*LNLS*)

e-mail: ingrid.barcelos@lnls.br

Phyllosilicates emerge as a promising class of large bandgap lamellar insulators. Their applications have been explored from the fabrication of graphene-based devices to two-dimensional (2D) heterostructures based on transition metal dichalcogenides with enhanced optical properties, optoelectronics, and polaritonics 1-4. Despite the extensive knowledge of the chemical composition of bulk phyllosilicates, retrieved from standard techniques such as Raman and IR spectroscopies, very little is known about those optical properties at the sub-micron spatial scale. Here, we provide an overview of IR s-SNOM for studying nano-optics and local chemistry of various 2D natural phyllosilicates including talc, phlogopite, and clinochlore5,6. Also, we bring a brief update on applications that combine natural minerals, graphene and phyllosilicate layers into functional heterostructures2,3. Additionally, we show that natural 2D talc supports hyperbolic phonon-polaritons (HPhP) similarly to the well-established 2D polaritonic hBN and α-MoO3 crystals in the far- and mid-IR range. Further, we highlight a few advances regarding nano-optical modulation in graphene-phyllosilicates devices driven by electrical control.

Thin-film optics is a key technology for the fabrication of miniaturized photonic devices, spanning from optical waveguides and photonic-integrated-circuits for optical signal processing, to multi-layered resonant structures and cavities for the confinement and spectral selection of the optical field. Active optical waveguides and photonic crystals are among the most versatile examples. One further step to add versatility to thin-film photonic structures involves the use of flexible materials. In fact, by adding mechanical flexibility to the rigid photonic systems, the range of applications greatly expands. However, passing from rigid to flexible substrates requires the development of suitable fabrication protocols, to preserve the optical and spectroscopic properties of the systems under mechanical deformation. We present the RF-sputtering fabrication of 1D photonic crystals and active Er^{3+} planar waveguides deposited on polymers and ultrathin flexible glass substrates. The structures deposited on ultrathin flexible glass show interesting results in terms of both optical and mechanical properties, making RF-sputtering a promising and scalable technique to fabricate flexible photonic devices [1,2]. Moreover, we report on the spectroscopic study of a 1D photonic crystal, fabricated via RF-sputtering on a flexible thermosetting polymer, in different bending conditions.

Polymorph tungsten oxide and its sub-stoichiometric phases (WO_{3-x}) have an extraordinarily broad range of possible photonic applications, from electrochromic layers in smart windows, to UV optical detectors, full-optical chemical sensors and photo-electro-catalytic membranes. We focus on Radio-Frequency (RF) magnetron sputtering deposition as a broadly versatile method to synthesize WO_{3-x} in different stoichiometries and nanostructures, easily up-scalable to industrial processes. We report on WO_{3-x} films fabricated under different recipes, which deeply differ in terms of possible applications. Optical-grade compact WO_{3-x} films can be fabricated by non-reactive magnetron RF-sputtering deposition from a WO_3 target at room temperature, followed by thermal annealing to tailor stoichiometry and structure. Films transparent in the NIR and electrically conductive can be obtained, that perform well as transparent contacts [1], but also insulating films, with the possibility to embed them into multi-layered IR resonant photonic structures for opto-chemical sensing [2]. Nanoporous WO_{3-x} photoelectrodes for green H_2 production are obtained from metallic W target, by RF-plasma sputtering process in a diode configuration in a reactive 40% O_2/Ar atmosphere. By changing the total gas pressure in the growth chamber, at same partial O_2 pressure, a bilayered diode-like structure is formed, which improves photoelectron transfer and decreases the interfacial resistance (Rct), leading up to about a 30% increase in photo-electro-catalytic (PEC) performance compared to monolayers coatings and to a 93% faradaic efficiency, which is among the highest reported so far for WO3 photoanodes [3].

Incorporating specific nanoparticles to induce new functionalities in optical fibers

Younes Messaddeq[1]

[1]Université Laval

e-mail: younes.messaddeq@copl.ulaval.ca

Engineering silica optical fibers by nanoparticle doping is a promising technology that allows the introduction of new functionalities and extends their applicable fields. However, the knowledge gap about the impact of the extreme fabrication temperatures on the nanoparticle features prevents the field progress. Herein, we demonstrate that the particularities of fiber fabrication, such as fast-heating rates and quenching heat treatments, can be leveraged to explore unlikely phenomena at the nanoscale under standard laboratory conditions. We have explored the incorporation of several spherical nanoparticles such as Ca-, Sr-, Ba-based nanoparticles and more recently cubic-shaped and rod-shaped YPO4 nanocrystals. Structural and anisotropic differences allow engineering differently their shape and composition in the fiber core by tailoring the drawing temperature, as revealed by a thorough study consisting of scanning electron microscopy (SEM), high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), electron energy loss spectroscopy (EELS), and high-resolution transmission electron microscopy (HRTEM). During this presentation we will show the possibility of doping optical fibers fabricated by modified chemical vapor deposition (MCVD) and the stability of the specific formed phases. These findings open up new avenues to study shape-dependent properties of rare-earth orthophosphate (REPO4) nanostructures, among others, in optical fibers which will allow incorporating unprecedented functionalities and will have an impact in several fields of application, such as fiber lasers and optical fiber amplifiers, among others.

Managing Nanomaterials for Boosted Random Lasers Performance: Basics and Multidisciplinary Applications

Anderson S. L. Gomes[1]

[1]Universidade Federal de Pernambuco (*Física*)

e-mail: andersonslgomes@gmail.com

Random Lasers (RLs) are low coherence optical sources whose optical feedback mechanism responsible to sustain laser oscillation arises from light scattering in disordered nanostructures, instead of two set of fixed mirrors as in conventional lasers. Therefore, RLs rely heavily on managing nanomaterials for optimum performance. In this talk, I shall review the basics of RLs and the role of nanomaterials in their design. Recent developmentsand multidisciplinary applications will be highlighted.

Nanomaterials properties for photonics applications

Isabel Cristina dos Santos Carvalho[1]

[1]Pontifícia Universidade Católica do Rio de Janeiro (*Física*)

e-mail: isabel.carvalho@puc-rio.br

Nanomaterials have attracted a great deal of attention due to their increasing number of photonic applications. Here, we investigate the optical properties of various nanomaterials for applications in random lasers, nonlinear devices, and plasmonic biosensing. The materials studied are quartzite, as scatters in random laser (RL) [1], silica-based systems for plasmonic biosensing, and an organic crystal for second harmonic generation (SHG).

In the RL configuration, with a concentration of 0.5mg/mL Quartzite/Rh6G in Ethyleneglycol, we verified a decrease of 91% in the FWHM, with a threshold energy of ~0.3mJ. We also performed simulations to explore the geometry of nanoparticles for RL systems.

For potential applications on biosensing, we studied the optical properties of systems composed of gold nanoislands biotin-functionalized to detect avidin, at the surface of silica (SiO2) xerogels monoliths.

An average redshift of 52 nm was observed in the Localized Surface Plasmon absorbance peak of all tested concentrations.

For the nonlinear optical characterization of a nanomaterial, a crystal built up from 2-aminopyrazine as a cation, with N1 protonation and dihydrogen phosphate as anion [2] was probed with Nd:YAG laser (1064 nm, 900 mW). The SHG light was detected and the FWHM of the 532nm pulse train was ~1.33 shorter than that of the IR pulses. Also, an angular dependence of the SHG light intensity was observed.

Photonic Nanostructures for Energy, Sensing, and Photothermal Applications

T. Randall Lee[1]

[1]University of Houston (*Chemistry*)

e-mail: trlee@uh.edu

This presentation will describe the fabrication and characterization of a variety of photonic nanostructures and their emerging applications. Examples will include (1) Au nanoparticles, Ag nanoparticles, and hollow Au-Ag nanoshells as supercapacitor materials, (2) Au nanostars, Ag nanostars, and hollow Au-Ag nanostars for sensing, and (3) various photonic nanostructures with near-infrared extinctions for photothermal modulation of shape-memory polymeric structures. Details of the synthesis of these materials will be discussed along with details of their structural characterization, optical characterization, and photonic-driven materials performance. The exploration and development of these photonic systems will not only expand our fundamental understanding of the relationships between nanoparticle structure/composition and photonic response, but will also lead to advances in nanoparticle-based applications in energy, sensing, and photothermal modulation.

Photonics at high-temperature regimes with refractory materials

Marina S. Leite[1]

[1]University of California, Davis (*Materials Science and Engineering*)

e-mail: mleite@ucdavis.edu

Refractory metals and dielectrics are a promising material alternative for optical devices that operate at ultra-high temperatures because of their high-temperature stability and suitable optical properties. Yet, most prior reports have used their room-temperature permittivity when designing structures and characterizing their performance. We present a comprehensive analysis of the optical properties of refractory materials for high-temperature photonic applications, including three examples. First, we experimentally demonstrate vivid color pixels with potential stability >1,000 oC [1]. Second, we introduce a paradigm for materials' screening for thermophotovoltaic optical emitters, where we identify combinations that enable theoretical power conversion efficiency >60% [2]. Third, by combining in situ experiments up to 1,500 oC with calculations we present some examples of optical emitters and superabsorbers that combine high thermochemical stability with excellent optical behavior [3]. Overall, the use of refractory materials is enabling photonic devices that are stable under extreme temperature conditions.

e-mail: zlu@univ-cotedazur.fr

Among the diversity of existing materials studied, nanoparticles-containing optical fibers are studied for the realization of lasers and sensors [1]. All these applications depend on our ability to control the characteristics of the nanoparticles in the fibers. To achieve this goal, we will discuss on two routes, both based on preforms prepared by the MCVD process. First, we will discuss on a route to obtain crystalline particles in as-drawn fibers [2]. Here, solution doping was used to embed YbPO4 crystals in the silica soot. We demonstrate, using scanning/transmission electron microscopes and confocal Raman microscope characterizations, that YbPO4 crystals not only survive the MCVD process but also the drawing process despite the high temperature involved (up to 2100 ◦ C) during fabrication processes. The second route deals with the control of the drawing parameters. It allows to control the shape and the size of the nanoparticles as they can elongate or break-up depending on the drawing temperature [3]. All these results allow to achieve a real engineering of the characteristics of the nanoparticles.

Relationship between structure and nonlinear optical response in nanostructured materials

Raúl Rangel-Rojo[1], Karen Yahaira Raygoza-Esquivel[2], Jacob Licea-Rodríguez[1], Israel Rocha-Mendoza[1], Paulina Segovia[1], Alicia Oliver[3], Tiziana Cesca[4], Giovanni Mattei[4]

e-mail: rrangel@cicese.mx

Nanostructured materials have attracted considerable attention for their optical properties, in particular for their large nonlinear response, and their potential for different applications such as information processing, and biological and chemical sensing, to name a few. The main reason for this is the ability to tune the optical properties by manipulation of the composition, structure and symmetry of the composites. For second-order, and to a lesser extent also for third-order nonlinear processes, the response is highly dependent on the symmetry of the material structure. It is this dependence of the response on material symmetry that makes nonlinear optics itself an interesting tool for probing the nanoscopic structure of the materials by means of merely macroscopic measurements. In this work we present results for the study of the structure of different materials employing nonlinear measurements. On one hand we present a study of second harmonic generation in elongated metallic nanoparticles embedded in glass, which have random positions but are aligned in a preferential direction. On the other hand, we also present second harmonic generation and nonlinear absorption studies in hexagonal arrays of metallic nanoprisms. In all cases the polarization dependence of the response observed is related to the structure and symmetry of the materials, through modelling of the nonlinear response, finding that we can indeed relate the observed response to the nanoscopic structure of the materials studied.

Second Harmonic Scattering of Nanoscale Materials : From Incoherent to Coherent Scattering

Pierre-Francois Brevet[1]

[1]University Claude Bernard Lyon 1 (*Institut Lumière Matière (ILM)*)

e-mail: pfbrevet@univ-lyon1.fr

Second Harmonic Generation (SHG) is encountered in its standard form in macroscopic non-centrosymmetric materials where phase matching drives the resulting intensity. At the nanoscale, phase matching no longer dominates and one can access fine details of the material quadratic susceptibility. However, the breaking of the phase matching condition enables as well the possibility to observe SHG scattering. The loss of coherence nevertheless is not complete. The presentation will address this question. In a first part, I will discuss incoherent SHG scattering with nanoparticles dispersed in a liquid solvent. In the particular case of nanoparticles, I will explore further the delicate balance between composition, size and shape and propose potential applications [1, 2]. I will further question the possibility of single nanoparticle measurements with control over the nanoparticles, opening new possibilities for applications. In a second part, I will address the case of the existence of a coherent contribution besides the incoherent one. To this purpose, I will describe the case of neat liquids and show how short range interactions can be accessed using SHG scattering [3].

e-mail: joao.antonio@unesp.br

Europium β-diketones (Eu^{3+}) complexes are known to exhibit interesting luminescent properties in the red region, making them excellent candidates for bioimaging or temperature sensing purposes [1]. However, their practical use is, sometimes, compromised due to their solubility and their prominent excitation by ultraviolet radiation [2]. Thus, the objective was to develop a smart nanomaterial based on the anchoring of the [Eu(TTA)3ephen] complex on the surface of upconversion nanoparticles (UCNP) doped with thulium ions ($LiYbF_4:Tm_{0.5}@LiYF_4$) and to evaluate the energy transfer processes between the particle-europium complex. For this, UCNP was obtained by the thermal decomposition method, followed by a coating with a thin layer of silica, which was later functionalized with the luminescent complexes. Overall, UCNP showed high-homogeneity with an average diameter of 30 nm after silica coating. XRD, TEM, EDS, FTIR, XPS, and zeta potential confirmed the structure and functionalization of the nanoparticles. By photoluminescence, UCNP showed characteristic emission of the Tm^{3+} ion in the ultraviolet, blue, red, and near-infrared regions when excited at 980 nm. In the presence of the Eu^{3+}-complex, UV-thulium emission disappearance since these photons are absorbed by the ligands coordinated to the Eu^{3+} ions that act as an antenna promoting their subsequent red emission. Initial tests between 15 and 50°C indicated that the sample has potential use as a two-center ratiometric thermometer since the luminescence intensity ratio (LIR) between different Tm^{3+} and Eu^{3+} transitions resulted in high relative thermal sensitivities of up to 1% $°C^{-1}$ at 50 °C.

e-mail: emanuel.pinheiro@ufpe.br

Luminescent materials have been investigated for optical thermometry under different underlying physical mechanisms, and most of the researchers have been focusing on the seeking of new functional materials in order to improve the sensitivity and thermal resolution of thermometers to mainly spread its application for a clinical level. However, the accuracy of those thermometers is still considered unsatisfactory for applications at the nanoscale. As we show in the manuscript, the uncertainty, especially in real-time measurements, can be due to intrinsic fluctuations of the spectrometer from one acquired spectrum to the next. Those fluctuations are present even for large signal-to-noise ratio. Then, we exploited Automated ML (AutoML) tools to search in a wide range of models and hyperparameters and identify the optimal solution for luminescence thermometry via genetic programming. The best ML algorithm provides optimal responses (larger than 5.5×) when compared with traditional luminescence thermometry methods. As a proof-of-concept, we investigated low sensitivity Nd3+ doped YAG particles under excitation at 760 nm and the results pointed out that using artificial intelligence is the direction for a possible clinical-level application of luminescence nanothermometers. Although tested here only for low sensitivity Nd3+ doped YAG particles, the methodology can be applied to any photoluminescent material and excitation wavelength. Therefore, in order to make our findings accessible to a broad audience, we made our algorithm open-source code, which was designed to be accessible to individuals who have no programming experience, with the goal of facilitating reproducibility and extension.

Co/Nb modified barium titanate synthesis via sol-gel method for transparent photonics applications

Rodrigo Nunes[1], Alysson Martins Almeida Silva[2], Luiz Fernando Lima[3]

[1]Universidade de Brasília (*Departamento de Engenharia Mecânica*) , [2]Universidade de Brasília (*Engenharia Mecânica*) , [3]Universidade Federal de Minas Gerais (*Departamento de Química*)

e-mail: rodrigonunesunb@gmail.com

Barium titanate is a lead-free perovskite that can present numerous interesting properties for a variety of applications, from bioengineering to photonics. Regarding the last one, barium titanate is known for yielding photoelectric effect [1], although its wide band gap restricts its efficiency. This wide band gap actually represents an obstacle for efficient photonics applications, thus it is imperative to narrow its band gap to achieve more prominent results. The present work aimed to modify barium titanate band gap by introducing both cobalt and niobium precursors as an attempt to dope its lattice and study band structure modification. The synthesis was made via sol-gel, and the samples were analyzed by XRD, SEM and HR-TEM imaging, UV-Vis, FTIR and Raman spectroscopies. XRD data showed a structure modification from tetragonal in the pure sample to pseudo-cubic in modified samples due to oxygen vacancies stabilization [2], also presenting peak shifting that indicates lattice doping. From UV-Vis spectra it was possible to notice that classic indirect band gap was not changed for all samples, remaining at 3.5 eV, although direct band gaps with values between 1.9 and 3.1 eV emerged from modified samples through band tailing, also it is suggested that a heterojunction was formed in modified samples [3].

e-mail: ezequiel.tosi@csic.es

ZnO nanowires (NWs) are being studied due to their promising applications in e.g. photonics, optoelectronics, solar cells, sensors and actuators. A few years ago, free standing membranes consisting of entangled ZnO NWs were developed by some of the authors on seed-free compacted graphite flakes [1]. The excellent UV emission of this hybrid material as probed by photoluminescence (PL) experiments and their free-standing nature gave clear indication that these membranes are very interesting for several technological applications. However, the origin of such large UV emission remained an open question. In this work, we study the emission of free standing ZnO/graphite membranes through time resolved and temperature dependent PL measurements. The samples were fabricated by vapor transport at high temperature in a tubular furnace under controlled (Ar+O_2) atmosphere. The NWs grew on catalyst-free graphite flakes that had been mechanically compacted within an alumina boat crucible. The self-supported membranes detached from the crucible base by exfoliation of the graphite substrate following thermal contraction during cooling. The PL time decay was analyzed in terms of decaying functions and time constants. A long lifetime component in a biexponential PL decay was inferred, which seems to be behind the large UV emissions detected at room temperature. Temperature dependent PL measurements reveal relatively low contributions from nonradiative recombination channels at room temperature, and a fine structure due to complexes emitting in the UV. The overall analysis indicates a low density of nonradiative recombination centers resulting from low precursor velocities achieved through a special geometry used during the vapor transport synthesis.

e-mail: otavioojoliveira@gmail.com

Climate change demonstrates the need to deploy renewable and CO_2-free energy in the coming decades. Solar energy, in particular photovoltaics, can play an important role in providing carbon-free energy [1]. The market for photovoltaic technologies is mostly dominated by silicon-based cells, corresponding to 90%. Silicon offers good stability and is the second most abundant element in the Earth's crust. However, the efficiency of silicon-based cells is limited by several factors, such as the intrinsic ones: transmission and thermalization, and the electronic ones: contact voltage, recombination, interface junction, and reflection. In this work we address thermalization losses, where the downconversion mechanism is proposed to overcome this problem. Therefore, the objective of this work is to study materials with the property of converting high energy photons into low energy photons. Lanthanides are good candidates to extend the functioning of silicon-based cells into the ultraviolet region, thus, europium (Eu) was selected as the downconversor agent to be used [2]. Starting from Eu chloride, different syntheses were tested, such as hydrothermal in the production of nanoparticles, for example. The synthed materials were deposited as thin films by spin coating and spray, the structural properties of the films were studied by XRD, the optoelectronic properties by PL, UV-vis transmission, and FTIR, and the morphological characteristics by AFM and SEM, with subsequent application of the films in the silicon cells and evaluation of the performance through the IPCE measurement.

e-mail: bh.costa@unesp.br

Optical materials doped with rare earth ions (RE) are the backbone of telecommunications systems [1]. In this regard, aluminophosphosilicate (APS) glasses are widely adopted for active optical devices due to the higher solubility of RE ions compared to pure silica matrix [2]. These materials are typically prepared by the melt-quenching method, the sol-gel method is an alternative synthesis route allowing the formation of glasses at relatively low temperature, under ambient atmosphere and green solvents, as well as the control of the concentration of phosphorus and aluminum incorporated. [3]. In this work, we investigated the luminescence at 1.53 μm from erbium-doped APS glasses with different Al/P ratios (0.6, 1.0 and 1.5) by exciting the samples at 980 nm. It was verified that the Al/P ratio equal to 1.0 and 1.5 resulted in higher emission intensity and lifetime values compared to the 0.6 ratio. We further investigated the dependence of the luminesce with Er3+ concentration in the range of 0.05% up to 0.5% mol, and our results show luminescence quenching at concentrations higher than 0.2 (mol.%), indicating clustering, and decreasing the lifetime, and intensity emission. Nonetheless, lifetime values were measured on the order of 1 ms due to the presence of OH groups in the glass caused by the sol-gel process. In order to eliminate theses OH groups, the materials were densified under vacuum at 900 °C, resultingin an enhanced lifetime. In situ UV generation by upconversion nanoparticles in photopolymerizable nanocomposites for disinfection of3D printing surfaces

Lays de Araujo Makiyama[1], Karina Maria de Souza Silva[2], Oscar Manoel Loureiro Malta[2], Petrus Santa-Cruz[2]

[1]Universidade Federal de Pernambuco (*DQF - Departamento de Química Fundamental*) ,
[2]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*)

e-mail: lays.araujo@ufpe.br

This work reports the synthesis and characterization of upconversion luminescent nanoparticles (UCNPs) of different fluoride matrices (CaF_2, LaF_3, Ca_2LaF_7) doped by the Yb^{3+}/Tm^{3+}pair, obtained by hydrothermal route, with the main objective of generating ultraviolet (UV) radiation in situ for decontamination purposes. To achieve higher UV emission intensity ($^1D_2 \rightarrow {}^3H_6$), a correlation was made between the concentrations of the Yb^{3+}/Tm^{3+}ratio and the IR→UV upconversion process, based on the Addition of Photon by Energy Transfer (APTE) mechanisms (Auzel Effect) between Yb^{3+}-Tm^{3+}ions and the cross-relaxation process between Tm^{3+}-Tm^{3+}ions [1-2]. A study of Fe^{3+}ions as a dopant showed that it contributed significantly to the IR→UV UC upconversion process. The obtained UCNPs had an average of 30 nm, presented in two crystalline phases: cubic (CaF_2) and hexagonal (LaF_3). The synthesized UCNPs were incorporated into a photopolymerizable resin for 3D printing and, as a result, a photopolymerizable UC nanocomposite (FPUCNC) was produced, which was subsequently printed in the shape of disks using mask stereolithography 3D printers (MSLA). Strategies are being established to increase the intensity of the UV emission as well as new mechanisms for Vis→UV UC instead of IR→UV UC to move excitation into the visible region. Microbiological tests to evaluate UV decontamination [3] generated in situ by UCNPs and FPUCNCs are being performed in collaboration with FIOCRUZ-PE using Zika as a model virus in a level-2 biosafety cabinet.

Magneto-optical sensors: Design and Development

Marcelo Nalin[1], Douglas Faza Franco[1]

[1]Universidade Estadual Paulista (*DAFQI*)

e-mail: marcelo.nalin@unesp.br

Magneto-optical materials have many applications in telecommunication systems, as Faraday isolators and rotators, can be used as sensors for both electrical and magnetical signals and have call attention for a variety of other fields such as those related to the monitoring of biosignals, including, but not limited to heart, muscles and brain. Despite the development of several devices based on single crystals, rare earths doped silica-based fibers and thin films, other challenges have emerged when the necessity of multifunctional devices with high sensibility is required. In this sense, the development of new glass compositions, suitable to produce more powerful devices, such as optical fibers, urges as the possible solution for an emerging market. In this work, we will show the study of promising glass compositions, the design of devices (optical fibers and discrete current sensors), as well as the trends in this multidisciplinary research field. The authors would like to acknowledge FAPESP (grant numbers 2012/07793-6) and SISFOTON-MCTi (CNPq-440217/2021-0) for financial support.

Nd^{3+}-Yb^{3+}:YAG thermal sensing for in vivo experiments:a comparison between materials synthesized by modified Pechini and solvothermal methods

Itália Vallerini Barbosa[1], Geraldine Dantelle[2], Alain Ibanez[2], Lauro June Queiroz Maia[3]

[1]Universidade Federal de Goiás (*Instituto de Fisica*) , [2]Université Grenoble Alpes (*Institut Néel*) , [3]Universidade Federal de Goiás (*Instituto de Física*)

e-mail: italia.vallerini@gmail.com

Nd^{3+}-YAG nanocrystals (NCs), known to exhibit two thermal couple levels from the $^4F_{3/2}$ excited state of Nd^{3+}around 940 nm, are currently evaluated as potential candidates for luminescent thermal probes within the first biological window BW-I, aiming biological applications. By luminescence intensity ratio approach, a relative thermal sensing (S_r) of 0.15 %·$K^{-1}$was determined in phantom tissues for detection and controlled thermal biomedical procedures [1], while Sr = 0.20 %·$K^{-1}$was obtained for NCs functionalized with a copolymer (PAA-b-PAM) [2]. Although the thermal sensing capacity of Nd^{3+}-YAG NCs, it is necessary to develop strategies to enhance the $S_r$value in order to reduce the thermal resolution (δ) value resulting in more precise temperature measurements. Therefore, we synthesized YAG co-doped with 0.25 mol% $Nd^{3+}$and varying from 0.10 to 2.00 mol% Yb^{3+}. In this work, we were able to increase three times the thermal performance of YAG nanocrystals thanks to the co-doping of YAG host matrix with different Ln^{3+}ions, in which we determined Sr = 0.67 %·$K^{-1}$and δ = 0.3 K. Our nanoprobes operate within the BW-II, with emissions at 1030 and 1064 nm. Moreover, we investigated the differences in the luminescent properties of these nanocrystals using two synthesis procedures, modified Pechini and solvothermal methods. In one hand, the first method allowed a facile route to produce nanocrystals and screening the Nd^{3+}-Yb^{3+}:YAG properties. On the other hand, the solvothermal allowed to obtain individual nanocrystals very well dispersed with morphology and size of 60 nm suitable for in vivo applications.

e-mail: claudevansousaf@gmail.com

All-inorganic lead halide perovskite nanoplatelets (PNPLs) have been explored in the last years because of their attractive optoelectronic properties such as high photoluminescence quantum yield and linear absorption coefficient [1]. Recently, we have shown that it is possible to form PNPLs superlattices formed by colloidal dispersion with viscous solvents such as Hexadecane [2]. In this work, we explore how the organization of PNPLs in superlattices influences their nonlinear refraction and two-Photon absorption (2PA) response. The study is performed in two PNPLs systems, two- and three-monolayer PNPLs, dispersed in hexane (C6, with viscosity coefficient at room temperature 0.31) and hexadecane (C16, with viscosity coefficient at room temperature 3.45). Our results indicate that 2PA cross section is six-fold enhanced when PNPLs are dispersed in C16, forming superlattices, compared to the analogs in C6, independently of the PNPLs thickness. It is still unclear the physical mechanism responsible for the enhancement of 2PA response for PNPLs organized in superlattice, however, one can speculate that this assembly of PNPLs breaks some of the selection rules for 2PA transition, increasing the density of allowed final states. Therefore, PNPLs superlattices emerge as an attractive alternative to increase 2PA cross sections in semiconductor nanomaterials.

e-mail: luana.oliveira@cetene.gov.br

High quantum yield values, functionalizable surface and good light absorption efficiency are characteristics that make quantum dots promising materials for optical applications.[1] To improve performance, the production of heterojunctions favors the electron transfer process, increasing the efficiency of the reaction at the interface by decreasing recombination centers.[2] In this work, the optical and observed properties of quantum dots of indium silver sulfides (AIS) stabilized by 3-mercatopropionic acid and co-stabilized by citric acid were evaluated. From the modulation of the Ag^{+}/In^{3+}ratio, the modulation of theemission spectra from 625 nm (0.07) to 675 nm (0.5) was verified, with quantum yields (QY)decreasing from 5.0% to 3.9%, respectively. Coatings with ZnS and CdS led tohypsochromic emission shifts and different QY% regimes, starting from AIS (0.18) with a progressive increase in QY%, from 9.0% (1:0.25) to 10.4% (1:2). Coatings with CdS showedan increase of QY%, up to 6.8% and 5.6% (1:0.25 and 1:0.5) and followed by a decrease inthe quantum yield up to 3.4% (1:2). Both regimes are associated with growth mechanisms of nanostructures, via ionic exchange, controlled by polarizability of d^{10}ions. Leading to substitution processes of $Cd^{2+}$and Zn^{2+}in Ag^{2+}positions, since they are soft acids and Pearson's border, but which lead to different regimes of core@shell and alloy structures. The photoluminescence lifetime decay curves showed that ZnS and CdS coatings increased the mean lifetime from 251 ns to mean values of 280 ns, but increased the relative abundance of excitonic processes in the luminescence. The coatings improved the charge transfer dynamics on the surface, directly implying a greater photoluminescent response.

e-mail: camila.lopesarruda@ufpe.br

New synthetic methodologies of quantum dots (QDs) look for simplicity, low cost and the non-use of toxic reducing agents have been the object of study in recent years.[1] Ternary nanocrystals, such as indium silver sulfide ($AgIn_5S_8$) stand out for their low toxicity when compared to systems based on cadmium and lead. In this work, an efficient route of synthesis via electrochemistry with a green character was used for $AgIn_5S_8$nanoparticles stabilized by L-glutathione, modulating the optical properties of light absorption and emission through different pHs and heat treatment.[2] It was observed that the nanocrystals obtained in the proportion 1:8, thermally treated for 60 minutes and at pH 7 showed better results of luminescence intensity, with a quantum yield of 3.1%. With the pH change, it was observed the displacement of the absorption bands and modification in the growth rate, as well as in the stability of the nanocrystal. To maximize the intensity, a coating with ZnS seeds electrochemically synthed and stabilized by GSH was carried out, with subsequent thermal treatment of the nanocrystals. The best results were from the use of the molar ratio of 1:1 between $AgIn_5S_8$and ZnS, forming nanocrystals with QY equal to 11.1%. The nanocrystals have a cubic crystalline structure, with peaks at 27.5, 46.3 and 52.7° for $AgIn_5S_8$, while they have peaks at 28.1, 47.4 and 55.4°. This 2θ displacement demonstrates the reduction of lattice parameters, resulting from the insertion of Zn^{2+}ions in the crystalline structure of $AgIn_5S_8$QDs in the position of Ag^+ions, forming the $AgIn_5S_8$@ZnS alloy. The results demonstrate a simple way of producing $AgIn_5S_8$@ZnS QDs with excellent stability and biocompatibility for respective biological applications without the need for further purification.

e-mail: thaisabrandao@usp.br

We will report in this presentation on the outstanding photochromic properties of naphthalene diimide (**NDI**) derivative bearing quaternary ammonium group (**DaO**). We found that a photoirradiation (λ = 365 nm) of **DaO** solutions triggers a fast color change, from colorless to dark red, that is not attributed to the photo reduction of the **NDI** core[1,2]. The observed phenomenon is accentuated for concentrations higher than 2 10^{-4} M and it is observed in different solvents such as THF, acetonitrile and water. We will show in this presentation that the photochromic behavior of **DaO** can be ascribed to a light-induced aggregation which leads to a significant modification of the electronic transitions resulting from the formation of H-type aggregates. In particular, our studies have revealed that these light-triggered self-assemblies can be dissociated by increasing the temperature to 70°C orby adding suitable salts (like $NaBF_4$). The reversible formation/dissociation of these assemblies was studied during irradiation/heating cycles followed by ^{1}H NMR and UV-vis spectroscopy measurements. Our results also support the conclusion that singlet oxygen is formed in solution when irradiation is performed under aerated conditions, which contrasts with previous reports demonstrating that aggregation usually decreases the sensitization yield.

Photonic inorganic materials containing lanthanides for random lasers, luminescence nanothermometry and optical waveguides

Lauro June Queiroz Maia[1]

[1]Universidade Federal de Goiás (*Instituto de Física*)

e-mail: lauro@ufg.br

It will be present interesting results of oxide nanomaterials doped and co-doped with lanthanides presenting emissions on visible and near infrared regions. The materials studied were prepared by soft-chemistry methods (Sol-gel process and polymeric precursors method) of the YBO_3, $YAl_3(BO_3)_4$, $Al_4B_2O_9$, $Y_2Ge_2O_7$, $Gd_2Ge_2O_7$, $Y_2Ba_3B_4O_{12}$, beta-BaB_2O_4, $Y_4Al_2O_9$, and AMPYZCAD, containing Er, Eu, Nd, Tb, Tm, and/or Yb for random lasers, lighting devices, displays, nanothermometry and/or optical waveguides applications. We characterized and analyzed the structural, microstructural, and spectroscopic properties, by using X-ray diffraction (XRD), high-resolution transmission electron microscopy (HR-TEM), selected area electron diffraction (SAED), diffuse reflectance spectroscopy, Raman spectroscopy, photoluminescence emission spectroscopy and lifetime measurements techniques. In summary, $YAl_3(BO_3)_4$ and YBO_3 doped with Nd can be used as efficient and stable random lasers operating in the infrared regions (mainly around 1064 nm); amorphous thin films of $YAl_3(BO_3)_4$ containing Er possess high quality for waveguides with good light coupling coefficient; YBO_3 and $Y_4Al_2O_9$ co-doped with Eu, Er, Nd, Tb, Tm present white light emission under excitation in the ultraviolet region, interesting for lighting and display device $Al_4B_2O_9$, $Y_2Ge_2O_7$, $Gd_2Ge_2O_7$, $Y_2Ba_3B_4O_{12}$ and beta-BaB_2O_4 doped with Nd or co-doped with Nd and Yb present good relative thermal sensitivity (S_r) values (higher than 0.23 %/K, with a maximum of 2.0 %/K, depending on the host composition and lanthanide concentration) being useful for nanothermometers in biological and opto-electronic system and AMPYZCAD have blue light emission with quantum yield around 80%, which could improve the efficiency of commercial LED's by coating with appropriate mixture of AMPYZCAD and PMMA. We acknowledge UFG-LabMic and CRTi for strctural results. This study was supported by CNPq, CAPES-Finance Code 001, FAPEG, FAPESP, FACEPE and I. Néel-CNRS-UGA.

Sulfur quantum dots obtained by femtosecond laser ablation of elemental sulfur in water

Vagner Bezerra dos Santos[1], Walter Mendes de Azevedo[1]

[1]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*)

e-mail: aldebaff.13@gmail.com

Sulfur quantum dots (SQDs) have been receiving great attention in recent years due its unique chemical, optical and biocompatible properties [1]. However, long reaction time, low photoluminescence quantum yield (PLQY), and very low S-to-SQDs conversion efficiency (lower than 1%) were reported as hindering to real applications [1,2]. Although, laser ablation is a known physical methodology applied to obtain nanoparticles of a lot of metals and oxides and to promote synthesis under unconventional conditions [3]. In this work, for the first time, a femtosecond laser was applied to synthe SQDs. For that, powder of elemental sulfur (S) was ablated in alkaline water solution containing PEG-400 through 1 h. Furthermore, the transparent brownish solution obtained was reacted with hydrogen peroxide solution at 3:4 ratio. As results, highest cyan emission was achieved using peroxide 3,75 %. The samples were analyzed by FTIR, Raman, TGA, XRD and luminescence measurements. Digital-image method was applied to determine the Hg concentration in environmental water.

e-mail: pizani@df.ufscar.br

The structural relaxation of glasses is directly related to the motion of atoms within the matrix, which is highly dependent on temperature. The motion of atoms may be either vibrational or translational. In the case of vibrational motion, the atoms vibrate around their equilibrium position with low amplitudes, and the configuration remains unchanged. On the other hand, in configurational relaxation, the atoms may diffuse from their equilibrium positions with increasing temperature. In this case, the timescale for configurational relaxation is much shorter than the experimental acquisition times, so time-averaged configurations are observed. In the present work, we will discuss and analyze in detail the results of the temperature effects on lead metasilicate, starting from the glass at room temperature up to 1220 K, 150 K above the melting point. The main experimental technique used was in-situ Raman scattering; some results were interpreted with the support of Molecular Dynamic Simulations.

The role of Eu^{2+}/Eu^{3+} ratio in Eu^{2+} based persistent phosphors explored by the case of $SrAl_2O_4$:EuDy

David Vieira Sampaio[1], Jerre Cristiano Alves dos Santos[2], Deyvid do Carmo Silva[3], John Ballato[4], Ronaldo Santos Da Silva[3]

The Eu^{2+}/Eu^{3+}ratio is a critical parameter that significantly affects the performance of Eu^{2+}-based persistent phosphors. Despite its importance, this ratio has often been overlooked, making it challenging to isolate other influences such as dopant concentration, particle size, or crystallinity. In this study, we aimed to provide valuable insights into the relationship between experimental conditions and the Eu^{2+}/Eu^{3+}ratio, as well as the luminescent properties of the $SrAl_2O_4$:EuDy phosphor. To achieve this goal, we produced ceramic samples under different atmospheric conditions and various concentrations. A low reducing atmosphere was mimicked by laser sintering, and a high reducing atmosphere was used by vacuum traditional sintering. We used X-ray diffraction, electron microscopy, X-ray absorption, and photoluminescence techniques to analyze the samples. Our results indicate that the dependence of the Eu^{2+}/Eu^{3+}ratio on dopant concentration is different under ambient and vacuum atmospheres. Specifically, the ratio exhibits a stronger dependence on concentration in the low reducing atmosphere compared to the high reducing atmosphere. Furthermore, we found that the ratio is a more relevant factor than the dopant concentration in determining the luminescent properties. Finally, we propose that the Eu^{2+}/Eu^{3+}ratio should be considered in conjunction with other factors to fully understand the luminescent properties of Eu^{2+}-based phosphors.

The role of intermolecular interactions in the luminescence of Eu^{III}-phosphor incorporated inpolymeric films

Leonardo Figueiredo Saraiva[1], Airton Germano Bispo Junior[2], Sergio Antonio Marques de Lima[3], Ana Maria Pires[3]

e-mail: leonardo.f.saraiva@unesp.br

The remarkable technological progress has led to a significant increase in the demand for optical materials, and tuning their photophysical features is crucial to enhance their luminescence, which can be done by combining spectroscopic and theoretical approaches [1]. Therefore, we present a theoretical protocol based on modelling the interfacial interactions in the composite based on the $SrY_2O_4:Ce^{IV/III}$(2at.%),Eu^{III}(3at.%) phosphor and the poly(methyl) methacrylate polymer (PMMA). All the calculations were performed using the GFN*n*-xTB code considering 50 monomers of the polymer around a 2×2×2 supercell ofthe phosphor, where eight Y^{III}sites were replaced by Eu^{III}. The simulation furnished information about the interactions, while their effect on the Eu-O bonds was obtained froma pseudo-diatomic model. SEM images revealed that increasing the phosphor quantity in the composite resulted in coarser films due to the agglomeration of the phosphor particles. Agglomerates were consequences of the polymer-phosphor intermolecular interactions, as illustrated from calculations, where Eu^{III}directly interacted with organic groups of the polymer. Decreasing the distance of the interacting atoms led to the strengthening of the intermolecular forces, affecting the photophysical features of the films. Stronger interactions promoted angular and bond length variations of the axial oxygens in the EuO_6polyhedra, leading to changes in the intensity parameters ($\Omega_{2,4}$). Hence, a computational methodology was developed to derive the influence of structural features on the photophysical aspects of the films in suitable accordance with the spectroscopic data. Accordingly, this protocol contributes to a better understanding of LnIII-based films, helping to bridge the gap to design strategies to enhance their performance.

e-mail: padilha@ifi.unicamp.br

Semiconductor colloidal nanocrystals (NCs) have emerged as a promising platform for applications that would benefit from large two-photon absorption (2PA) cross-section, as it has been predicted that quantum-confinement would enhance the oscillator strength for nonlinear optical transitions. However, after about two decades of intense study of 2PA in NCs, what are the lessons the community has learned from it? Here we will make an overview of the state-of-the-art of 2PA studies in quantum-confined semiconductors and show strategies to control the nonlinear absorption response of these nanomaterials. We show that, despite the fact that quantum confinement induced enhancement of 2PA in 3-dimensional confined semiconductors has not been demonstrated unambiguously yet, there are methods to obtain high 2PA response in nanomaterials by shape and heterostructure engineering. Using different types of core/shell heterostructure, we show that it is possible to decouple the magnitude of the nonlinear response from the emission wavelength, obtaining nearly one order of magnitude enhancement of 2PA cross-section in quasi-type-II CdSe/CdS core/shell, without shifting their emission wavelength. This can be useful for applications going from two-photon excited lasers to multi-photon excited 3D microscopy.

Biological temperature range using a optical thermometer based in $CsPbI_3$ perovskite and Er^{3+}

The determination of temperature is a crucial parameter in numerous biomedical and industrial applications. In this context, the utilization of an optical thermometer presents a highly promising alternative to conventional thermometers, owing to its rapid response and non-contact capabilities. In the last decade, optical thermometry was studied using the luminescence of coupled levels of rare earth ions such as Er^{3+}. Moreover, the optical thermometers based on Er^{3+}have been used as a primary thermometer due its fluorescence intensity ratio responds linearly to changes in temperature mainly in the biological temperature range. In other hand, perovskite halide semiconductor nanocrystals ($CsPbX_3$, X = Br, Cl, I) present absorption and optical emission bands that are adjusted in the region of the visible spectrum (400 - 750 nm) [1]. These nanostructured materials have strong luminescence, and the absorption range is inserted in the first biological window. In this work, the glassy matrix doped with $CsPbI_3$and codoped with the Er^{3+}ion concentration varying in relation to the mass content of the glass matrix of 1 and 2% is being studied. The samples were characterized using Transmission Electron Microscopy/Electron Diffraction, Photoluminescence and UV-Vis Spectroscopy. This system is a primary thermometer, has a value of 4.3 K^{-1} to relative sensitivity at 298 K and shows to be an interesting candidate to an optical thermometer with application in the range of 298 to 363 K.

e-mail: wanessafonso@aluno.puc-rio.br

We investigate the optical properties of systems comprised of functionalized gold nanoislands on the surface of silica xerogel monoliths for the development of biosensors based on Localized Surface Plasmon Resonance (LSPR). LSPR is highly sensitive to changes in the nearby chemical environment, making it an ideal choice for biosensors. To carry out this study, we functionalized the xerogel surface with biotin to detect avidin in aqueous solution. The silica gels were obtained by two-step sol-gel process from TEOS:H2O:Ethanol solution, using HCl and NH4OH solutions as catalysts. The gels were then aged and dried at 700oC to create the xerogels. To form the gold nanoislands, a thin film of 20 nm Au was deposited on the top surfaces of the xerogels and subjected to heat treatment up to 600°C. The resulting Au@SiO2 xerogels exhibited a color change from blue to pink, characteristicof gold nanoparticles. The surface of the AuNP@SiO2 xerogels were then functionalized intwo steps with cysteamine (CA) and N-hydroxysuccinimide-biotin (NHSB) for the detectionof avidin in an aqueous solution. The functionalization process was monitored by UV-Vis optical absorbance for each step, and aqueous solutions with different concentrations of avidin were used to test detection and sensitivity. An average redshift of 52 nm was observed in the absorbance spectrum of all tested concentrations (10-6M, 10-7M, 10-8M,10-9M and 10-10M), indicating that this system is a promising structure for plasmonicbiosensor applications.

Plasmonic nanoparticles have been widely studied due to their special optical properties. Particularly, the study of light interaction with metallic nanostructures is rapidly emerging in plasmonic devices that are associated with analytical applications such as Surface-Enhanced Raman spectroscopy (SERS). Herein, we synthesized copper, silver, and gold nanoparticles (CuNPs, AgNPs, and AuNPs) for comparison of enhanced-Raman signal efficiency, using Violet Crystal and Rodhamine 6G (VC and R6G) as probe molecules. We also evaluated the analytical performance using Levodopa (L-Dopa), with the SERS substrates fabricated from the self-assembly methodology (SAM). Silicon substrates were functionalized with (3-mercaptopropyl)trimethoxisilane (MPTMS) and (3-aminepropyl)trimethoxisilane (APTMS) for further metallic covalent interactions. Surface-enhanced Raman and Surface-Enhanced Raman Resonant Scattering (SERS and SERRS) were evaluated for the plasmonic platforms using different lasers (532, 633, and 785 nm) for the respective molecules. Effectiveness syntheses were confirmed by UV-vis spectroscopy with plasmon bands at 582, 479, and 531 nm, corroborated with STEM-SEM micrographs that displayed a good homogeneity distribution. Additionally, the high control size distribution of metallic nanoparticles was also checked with dynamic light spectroscopy (DLS) and inductively coupled plasm mass single particle. The SEM micrographs reveal that the SERS substrates have an excellent metallic deposition on the Si surface, with favorable hot spots coupling to detect trace levels of molecules. A detailed Raman mapping was achieved to detect VC, R6G, and L-Dopa in the 10^{-3}–10^{-9} mol L^{-1} concentration range, with good reproducibility and sensitivity obtained in the analytical curves.

Carbon dots (CDs) are nanomaterials with promising applications in several areas such as optoelectronics and biomedicine due to their low toxicity and strong luminescence intensity. Understanding the emission and bandwidth of the fluorescence spectrum is still a challengein the scientific community due to the dependence of emission on the excitation wavelength. In this work, the photoluminescence properties of carbon dots obtained from microcrystalline cellulose (MCC) were studied [1]. The optical properties were studied through measurements of photoluminescence (PL), photoluminescence excitation (PLE), and absorption. Systematic adjustments were made through Gaussian deconvolution of the PL spectrums and the coupling between electronic states was analyzed through PLE and optical absorption measurements. From the Gaussian adjustments, bandwidth values of ~25 nm and ~100nm were found for the emission associated with the core and the surface states respectively, these values are consistent with the bandwidth of the PLE spectra with tuned detection in these states. As evidenced by the results, there are contributions from the core and surface functional groups in the luminescence emission of CDs [2]. Furthermore, with recent analyzes that attribute the radiative emission of CDs only to the surface trap states, we observed that the core present emission and absorption of light for samples with specific pH and reaction times. These results should contribute to the understanding of the electronic transitions of CDs for applications related to the luminescent optical properties of these nanomaterials.

Determination of the band positioning of nanocrystalline semiconductors by cyclic voltammetry

e-mail: paulo.livramentojunior@ufpe.br

The determination of the band positioning of semiconductor nanocrystals is a fundamental step in the determination of possible applications and performances of the materials. In this sense, electroanalytical techniques are powerful alternative strategies to XPS/UPS analysis. In this work, we evaluated the band positioning from the d10 MS ion sulfide series (d10 M=Zn2+, Cd2+, Hg2+ ions) with zinc blend structure, through cyclic voltammetry. The quantum dots (QDs) were electrosynthed in a cavity electrochemical cell, through a chronopotentiometric procedure (30 mA, 12.5 C), forming in situ HS- ions, using L-glutathione as a stabilizer in a proportion (1 :3:6, HS-, M2+, GSH), provide the formation of ZnS, CdS and HgS nanocrystals.[1] Being heated for 30 min under reflux. From the absorption spectra and the construction of Tauc curves, the values of optical bandgap (Egopt) of the ZnS QDs (λabs = 325 nm, Egopt = 3.80 eV), CdS (λabs = 380 nm, Egopt = 2.65 eV) and HgS (λabs = 800 nm, Egopt = 1.54 eV). ZnS and CdS nanocrystals present optical emission (λem) at 442 and 490 nm, respectively. HgS in the near infrared region. Relative band positioning were determined by cyclic voltammetry, with a glassy carbon electrode as a working electrode, Pt as a counter electrode, and Ag/AgCl 3.5 M as a refstabilizer, For measurements at pH 4, the cathodic peaks -1.26 V ZnS, -1.15 V CdS, -0.98V HgS (V vs. Ag|AgCl) were verified, evidencing the influence of pH on the deprotonation ofthe stabilizer and making the interface accessible of quantum dots. The experimental datawere compared with those calculated using Mulliken''s absolute electronegativity,[3] and small deviations between the electrochemical method (cyclic voltammetry) were verified.

The phosphors-in-glass (PiG) finds applications in electronic devices for conventional lighting and in the high power automotive headlight industry [1,2]. This work developed PiGs materials from oxyfluoride phosphate glass system and TR-doped YAG (TR=Sm^{3+}, Eu^{3+}, Tb^{3+}or Dy^{3+}in content of 0,01 mol). The glass $42P_2O_5$-50KF-$8Al_2O_3$(PKAl) in mol% was synthesized by the conventional melt-quenching, in air atmosphere. The YAGs were synthesized by the sol-gel method. For the preparation of the PiGs an amount of x=10, 20 and 30 wt% of doped YAG was added to the glass matrix (100-x) by sintering (T = 420°C). The synthesized glass showed an amorphous characteristic verified by the XRD data and the phosphors showed a XRD pattern corresponding to the pure YAG phase. The PiGs analyzed by XRD showed peaks characteristic of crystalline materials of the YAG phase and an amorphous phase corresponding to PKAL glass. In the FTIR spectra, it was verified that the profiles of the samples of YAGs correspond to the FTIR spectra reported in the literature, as well as the synthesized glass and PiGs have characteristic bands of phosphate glasses. The excitation and luminescence spectra for doped samples showed characteristic bands of Sm^{3+}, Tb^{3+}, Dy^{3+}and Eu^{3+}ions. The increase in the luminescence intensity was proportional to the amount of YAG doped. These results show that doped PiG materials are good candidates for optical and photonic applications, with wide application possibilities.

Titanium dioxide (TiO_2) is a material widely used in photocatalysis applications, due to its high photoactivity and low cost[1]. In order to tune the properties of nanocrystals, doping with metal and non-metallic ions is performed. Doping alters the band gap, structural phase and size of TiO_2nanocrystals (NCs) [2]. Therefore, in order to investigate the effect of type and concentration of doping on the properties of TiO2 NCs, in this work we synthesized and characterized pure and doped TiO_2nanocrystals with calcium and europium ions. Vibrational, structural, optical and morphological properties were investigated using Raman Spectroscopy, X-Ray Diffraction (XRD), Optical Absorption (AO) and Scanning Electron Microscopy (SEM) techniques. Raman and XRD diffractograms confirmed the formation of TiO_2nanocrystals in the anatase phase. In the AO spectra, characteristic absorption bands of $TiO_2$and dopants were observed, and with increasing concentration there was a variation in the band gap of the nanocrystals. In the SEM images confirmed the formation of nanocrystals. Therefore, in this work it was demonstrated how the type and concentration of ions alter the structural, optical and and morphological properties of TiO_2nanocrystals.

Luminescent thermometry continues to be an important area of research due to the growing demand for increasingly smaller temperature sensors, as in the case of nanothermometers [1], and that they are increasingly efficient, for example, with greater emission and relative thermal sensitivity [2]. Based on this, in this work we investigate the structural and luminescent properties of host matrices based on sodium titanate, more specifically, undoped and Eu3+ doped sodium trititanate (Na2Ti3O7) and sodium hexatitanate (Na2Ti6O13), with focus on their potential use as luminescent thermometers. The influencesof Eu3+ doping and heat treatment (HT) on the structural and luminescent properties ofsodium titanate matrices were investigated. As a result, we found that both the Eu3+ ion concentration and the variation in the HT temperature influenced the transformation of Na2Ti3O7 to Na2Ti6O13. In addition, the increase in concentration intensified the luminescence intensity. However, high HT temperatures favored the decrease in emissionintensity. The sodium titanate matrix doped with 5% and thermally treated at 500 ºC wasthe one that presented the highest luminescence, and we found that the maximum relativethermal sensitivity obtained was approximately 0.34%C-1 at 25 °C, which is a value comparable to other luminescent materials presented in previous literature. Thus, we demonstrate that this material, specifically sodium hexatitanate doped with 5.0 mol% of Eu3+, is a potential candidate for luminescent thermometry.

Rare earth (RE^{3+}) ions doped glasses matrix are materials of high technological importance. Lately, these materials have been used as photonic devices, optical display devices, optical amplifiers, optical temperature sensors, optical thermometry, photovoltaic cells, NIR and visible lasers, nonlinear optical devices, etc. Particularly, in this work the thermo-optical and structural properties of the phosphate glass matrix (PANK) doped with $Nd^{3+}$with different concentrations of niobium oxide (Nb_2O_5) are being studied. This system was synthesized using the traditional melt cooling technique and are being characterized by analysis structural (X-Ray Diffractometer and Raman spectroscopy), optical (UV-Vis absorption spectroscopy and Photoluminescence) and thermal (Differential Scanning Calorimetry). The results show that the addition of Nb_2O_5in the phosphate glass matrix produces structural changes that alter the optical properties of the material, such as the increase of the refractive index and increase in the photoluminescence of rare earth ions. Thus, these glasses can be potential candidates for applications in photonic devices, such as: filters for UV wavelength, UV and IV band energy converters for visible, and in optical fibers in the third telecommunications window [1].

Ternary quantum dots I-III-VI2 or I-III5-VI8 have a luminescence dynamic associated with the scale and easy modulation via chemical composition, allowing extensive band engineering work. This work presents the modulation of the optical properties of glutathione-capped silver indium sulfide system (AIS QDs) when coated with binary nuclei of chalcogenides (MX, where $M = Ag^{+}$, Zn^{2+}, and In^{3+}; $X = S^{2-}$ and Se^{2-}). Evaluating the influence of the polarizability of cations and anions for the formation of heterojunctions or alloys, according to Pearson''s hard and soft acids and bases theory.1 Heterojunction formation was evaluated via the AIS/MX ratio, with respect to chalcogenides ($S^{2-}:X^{2-}$= 1:0.25, 1:0.5, 1:1, 1:2). QDs were characterized optically and structurally. The absorption spectra and Tauc curves showed trends regarding MS coatings: with small proportions of MS, hypsochromic shifts were verified, associated with the substitution of cations forming acceptor states ($Zn^{2+}_{Ag^{+}}*$) and donor states ($Ag^{+}_{In^{3+}}{}'$ and $Zn^{2+}_{In^{3+}}{}'$) By increasing the MS content (Ag^{+}, Zn^{2+}, and In^{3+}), bathochromic shifts are associated with the growth of nanoparticles. For In_2S_3, a decrease in quantum yield (R6G as standard) was verified. For MSe coatings, all samples showed a progressive decrease in quantum yields (QY%) from 29.2% for AIS to 17.8% (ZnSe), 11.1% (Ag_2Se), and 10.7% (In_2Se_3) ($S^{2-}:X^{2-}$= 1:0.5). MS coating led to QY% increase of 48.1% (ZnS), 34.3% (Ag_2S), and 30.3% (In_2S_3). The optical effects were more significant considering the interaction with Ag^{+} and Zn^{2+} ions, soft and border acids, respectively. These results allow us to single out trends and dedicate specific methods for engineering ternary semiconductor bands in water.

The optimization of solar cell performance remains a fundamental goal of the photovoltaic industry. An effective approach to achieve this objective involves managing solar spectrum radiation on the solar cell surface by covering it with photonic glasses [1]. Glasses doped with rare- earth ions have shown to be candidates to manage the solar cell spectrum for photovoltaic devices. In particular, Alumina-lead-germanate (GPA) glasses have demonstrated potential for photonic applications such as random lasers, multijunction solar cells and waveguides [1-3]. Here, the electrical response of a silicon solar cell covered with GPA glasses is investigated. Samples of GPA glasses doped with Eu3+ and Tb3+ ions and silver nanoparticles were fabricated using the melt-quenching technique [1]. Moreover, samples prepared without these nanoparticles were also prepared and used as reference. The current-voltage (I-V) curves of silicon solar cells covered with GPA glasses were obtained, and then, critical performance parameters, such as short-circuit current (Isc), open-circuit voltage (Voc), Fill Factor, and efficiency, were determined. The results showed that the photovoltaic device efficiency is increased when compared with the bare solar cell.

e-mail: rodrigo.silva@fis.ufal.br

Recently, a photon-avalanche-like (PA-like) process based on trivalent neodymium ions (Nd^{3+}) under an unconventional excitation at 1064 nm was demonstrated using stoichiometric $NdAl_3(BO_3)_4$ particles. Although the Nd^{3+} can emit radiation at 1064 nm efficiently, they present very small absorption at this wavelength due to the absence of resonant ground-state transitions. However, phonon-assisted excitation ($^4I_{9/2} \rightarrow {}^4F_{3/2}$ and/or $^4I_{11/2} \rightarrow {}^4F_{3/2}$) followed by cross-relaxation between one excited ion ($^4F_{3/2}$) with another at the ground state ($^4I_{9/2}$), and subsequent phonon emissions {$^4I_{15/2}$, $^4I_{15/2} \rightarrow {}^4I_{13/2}$, $^4I1_{3/2} \rightarrow {}^4I_{11/2}$, $^4I_{11/2}$}, provide two ions at the $^4I_{11/2}$ state, from which can occur the resonant excited-state absorption to the $^4F_{3/2}$ level. Reestablishing the sequence of events, the absorption of photons at 1064 nm can increase greatly. Besides the emission around 880 nm ($^4F_{3/2} \rightarrow {}^4I_{9/2}$), there are thermal excitations to upper-lying states, with subsequent emissionsin the visible and near-infrared regions (480-2000 nm). Here, we investigate the role of theNd^{3+} content on the PA characteristics in $Nd_xY_{1.00-x}Al_3(BO_3)_4$ particles with x ranging from 0.05 to 1.00. It is known that the replacement of Y^{3+} by Nd^{3+} into the $YAl_3(BO_3)_4$ crystalline structure can introduce strong modifications of the lattice properties as well as in the photoluminescence characteristics, such as luminescence concentration quenching and broadening of spectral lines. Despite that, we observe, for low x (≤ 0.20) an energy-looping preceding the PA-like that ensues for $x \geq 0.40$. It is associated to the proximity among the Nd^{3+} ions, fundamental to the electric dipole-electric dipole interaction responsible for the Nd^{3+} energy transfer {$^4F_{3/2}$, $^4I_{9/2}$} → {$^4I_{15/2}$, $^4I_{15/2}$}. We discuss the present results focusing on emerging technologies with development of ultra-sensitive thermal sensors, and super-resolution imaging thanks to the giant nonlinearities in the input-output power dependences.

Enhancing Second and Third Harmonic Generation with MoS_2 Monolayers on Silicon Nitride Waveguides

e-mail: mohd.rehan@mackenzista.com.br

Silicon optical waveguides have excellent scalability and readiness, but their optical properties, such as two photon absorption (TPA) and absorption at visible frequencies, limit their potential for optical frequency conversion applications [1]. Silicon nitride (SiN) emerges as a viable alternative to silicon, with proven performance in both near IR and visible applications. However, SiN's low Kerr nonlinear coefficient and centro-symmetric properties offer limited efficiency for nonlinear frequency conversion. Integrated SiN photonics structures with 2D materials offer a promising route to enhance nonlinear opticalproperties of this material. Transition-metal dichalcogenides (TMDCs), such as MoS_2, have optoelectronic characteristics like direct bandgap, robust valley polarization, and significant electric tunability which can be useful for various applications [2]. Many TMDCs are inherently non-centrosymmetric, making them attractive for second-order nonlinear optical effects, indeed, WS_2, MoS_2, and $MoSe_2$ have been used for second- and third-harmonic generation [2, 3]. In this work, MoS_2 monolayers were transferred on top of SiN waveguides to explore optical frequency conversion. Our results show an increase in second and third harmonic production due to integration of MoS_2on the waveguide while pumping with high power laser of 150 fs duration, and 750 W peak power at 1560 nm.

Eu^{3+}-doped SiO_2 –$Y2O_3$ -SnO_2 planar waveguides: refractive indexes and spectroscopic properties for application in optical sensors and amplifiers

Maria Vitória Guidorzi[1], Fernanda Hediger Borges[1], Rogéria Rocha Gonçalves[1] [1]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto da Universidade de São Paulo

e-mail: guidorzim@usp.br

Recent modern applications in the field of photonics have implicated the use of waveguides, mainly due to the growing demand for optical sources and amplifiers operating at wavelengths compatible with fiber communication technology. [1] In this sense, the purpose of this research was to study the properties of Eu^{3+}-doped SiO_2–$Y2O_3$-SnO_2planar waveguides. The films, with Si/Sn/Y ratios of 70:15:15, were prepared by a sol-gel methodology and deposited by the dip-coating technique onto 10 μm SiO_2–Si (100) p-type silicon and Si (100) silicon. The growth of films was followed by specular reflectance, where it was possible to observe the dependence of the number of interference fringes with the quantity of deposited layers. From the number of fringes and the position of their maximums and minimums it is possible to estimate the index of refraction and film thickness at each deposition [2]. The optical characterization was accompanied by m-line, obtaining the number of modes and propagation angles, as well as the effective refractive index of eachmode at different wavelengths in polarization function (TE and TM). The thickness andrefractive index values were used to understand better the influence of temperature and annealing time on the densification of the bulk films. The refractive index shows the densityof the films, achieving relatively high light confinement within the waveguide structure, andnegligible optical loss due to surface scattering. The annealing temperature, 900 °C, atdifferent times (until the refractive index stabilizes), has been shown to be enough to promote the densification, pore elimination, and increase and control the refractive indexvalues.

Random lasers (RLs) rely on obtaining laser emission in disordered systems with gain [1]. The RL characterization is usually performed by the observations of bandwidth narrowing, increasing in the slope efficiency, time shortening of the upper level of the RL transition, intensity and spectral fluctuations, and even photon statistics transitions when increasing the optical gain. However, the gain clamping, which is a known phenomenon in conventional lasers, i.e. lasers with well-defined cavity, was never investigated in RL. Here we realize an experimental-theoretical investigation of the gain clamping in RLs, and demonstrate that it can be used as an alternative tool to characterize the transition from spontaneous emission to the RL regime. Two different RLs were investigated: one based on Nd3+ ions in crystalline nanoparticles [YAl3(BO3)4]; and another based on rhodamine 6G molecules and titanium dioxide (TiO2) nanoparticles as scatterers. Despite these systems present distinct features such as quantum yields and fluorescence lifetimes, the gain clamping was observed in both, and corroborated with numerical simulations based on a rate equation system for the atomic populations, and the energies at the random and a fluorescence emission, whose transitions departure from the same level. In both systems, at the onset of the RL emission, the fluorescence demonstrated a saturation behavior, evidencing the gain clamping. As a consequence, the fluorescence presents low fluctuation for excitation pulse energy larger than the threshold, on the other hand of the RL emission, which shows large fluctuations. We discuss our observations on the light of the statistical mechanics, with the observation of Gaussian or Lévy probability distributions for the intensity fluctuations.

The green synthesis of metallic nanoparticles has been considered a promising and sustainable route due to the use of biological organisms, or parts of them that replace chemical reagents that may have a higher degree of toxicity [1]. Thus, phytochemical compounds from plant extracts are used as reducing and stabilizing agents to obtain metallic nanoparticles [2]. In this work, we synthesized gold nanoparticles (AuNPs) in different concentrations of gold solution (100 μL, 200 μL and 300 μL) through green synthesis using the extract of leaves of Hymenaea courbaril L. (Jatobá). The results showedsurface plasmon resonance (SPR) bands at 526 nm, indicating the formation of AuNPs. TheZeta potential analyses showed that the NPs surface has negative values of −17 mV, indicating good stability. The AuNPs have average hydrodynamic size ranging from 58 nmto 193 nm. The vibrational modes, characteristic of phytochemical compounds (flavonoids, terpenes and alcohols) present in Jatobá extract were observed by FTIR analysis. The thermo-optical properties were investigated by thermal spectroscopy, and showed values of thermal Diffusivity between 8x10−4 cm2/s to 10x10−4 cm2/s. The samples were tested for antibacterial activity with two different types of bacteria (gram positive and negative), and it was found that both NPS and Jatobá extract have antibacterial activity. These gold nanoparticles are promising material for future applications in nonlinear optical and health area.

e-mail: eduardom@alunos.utfpr.edu.br

The use of carbon nanomaterials, such as graphene, has become more interesting due to its fantastic properties, allowing several applications. The present work aimed the synthesis and characterization of mono/bimetallic gold or silver/copper NPs thin films with graphene sheets on silica substrate, in a single thermal synthesis step. For this, silica coverslips were cleaned and functionalized with (3-aminopropyl) triethoxysilane (APTES) together with the chosen metal and polystyrene (PS) as an extra carbon source and taken to a muffle furnace at 350 °C for 30 minutes. In the end of the synthesis steps, the films were characterized through UV-Vis spectroscopy, to verify their LSPR, X-ray diffraction (XRD) to verify the crystalline structure, thermal analysis and Raman spectroscopy (Raman) to confirm the synthesis of graphene and transmission electron microscopy (TEM) images to verify nanocopper shape, and the presence of 2D carbon materials. All films obtained with copper precursors showed signs of graphene sheets traces on TEM images. Thus, the use of PS as an extra carbon source resulted in a graphene amount increase with an environmentally friendly synthesis. Samples containing 1:100 of PS resulted in the TEM images a high amount of amorphous carbon mostly, in the 1:10 a mixture of amorphous material and graphene, and in the 1:1 samples showed mostly graphene. These data were confirmed through thermal and Raman analyzes for Cu and AgCu samples.

The development of bimetallic nanoparticles has been gaining prominence, due to their properties that may differ from the monometallic ones. Applications for these nanomaterials are, for example, in electronic circuits and solar cells. Synthesis routes that result in these materials deposited in substrates can facilitate their use in different devices. For this, our work aimed the synthesis and characterization of monometallic and bimetallic (silver and/or nickel) nanoparticles thin films on silica and FTO substrates, in a single synthesis step, witha thermal reduction of the metallic precursors. For this, after cleaning both substrates with HNO_3solution, they are rinsed with deionized water, and the substrates are dried with hot air and placed in solutions containing 3-aminopropyltriethoxysilane (APTES) in toluene (10% v/v) with the metals precursors ($AgNO_3$and/or $Ni(NO_3)_2$), remaining under 60 °C heating for3 hours. After that, the reduction of metallic ions was carried in a 300 °C muffle for 20 minutes, until complete the APTES pyrolysis and cations reduction processes. All different films were characterized by UV-Vis spectroscopy, to verify their Localized Surface Plasmon Resonance - LSPR, indicating the success of metallic and bimetallic films preparation by the proposed route. Transmission Electron Microscopy (TEM) images were performed to obtain information such as the nanoparticles average and shape in each sample, and to understand the structure of bimetallic films. Scanning Electron Microscopy (SEM) images, in progress, will allow analyze the homogeneity, composition and stability of the synthed films.

1,8- naphthalimides and 1,4,5,8- naphthalenediimides, as supramolecular units, are used as fluorescent glow agents, intracellular biomarkers, and model compounds for photoinduced electron transfer [1]. In this study, the investigation of the effect of amine concentration on the imidization of 1,4,5,8- and 1,8-anhydrides was carried out, taking into account that the amine-imide interaction during the reaction may lead to the formation of dyes with new photophysical properties, without, however, there being structural modification of the aromatic imide. Thus, using reactions between anhydride and amine in different percentages, it was studied the effect of the amine concentration in the synthesis of imide, in terms of coloration and brightness. Then, the respective crystals of these imides were obtained using ethanol as solvent. For the characterization of the materials melting point determination, infrared, X-ray and fluorimetry analyses were performed. For melting point analysis, it was obtained an average temperature of 171.8°C and for fluorimetry analysis the imides presented peaks around 464 nm, varying only in the intensity values. For the infrared analysis, it was possible to confirm that there was a reaction of imide synthesis, and all the characteristic peaks of an imide were observed. Despite the similarities in the characterization results, some imides presented different colorations, as well as their respective crystals, even though the using of a same solvent. So, it is possible to infer that the percentages of amine used were responsible for this change in coloration presented by the studied imides and the best percentage of amine to be used is above 30%.

Gold nanorods and CdSe nanocrystals are distinct types of nanomaterials with unique properties. Gold nanorods are elongated, rod-shaped particles composed of gold atoms, and find applications in various fields such as medical imaging, diagnostics, catalysis, and drug delivery. On the other hand, CdSe nanocrystals are spherical particles composed of cadmium selenide molecules, and are used in optoelectronic devices like solar cells, light-emitting diodes, and lasers. The energy transfer between CdSe nanocrystals and Au nanorods can occur through multiple mechanisms, including Förster resonance energy transfer (FRET), plasmon-mediated energy transfer, and exciton-plasmon coupling. FRET involves the transfer of energy between electronic excitations in two different molecules or nanostructures, typically mediated by dipole-dipole interactions. Plasmon-mediated energy transfer, on the other hand, is the transfer of energy between plasmons in two different nanostructures, such as CdSe nanocrystals and Au nanorods. In this work, three group of samples were studied. The first group are CdSe nanocrystals were synthetized using two different growing time to form different sizes of nanocrystals. The second group are the Au nanorods synthesized in order to obtain different aspect ratios using distinct $AgNO_3$concentrations during the synthesis. And the third group the mixture contends CdSe nanocrystals and Au nanorods. The samples have been characterized using photoluminescence and absorption spectra and thermal lens technique to determine the optical properties and the energy process transfer.

e-mail: edervgol@gmail.com

We experimentally evidenced the internal energy transfer (IET) in Co-doped Bi_2S_3Nanocrystals (NCs) embedded in borosilicate host glass produced by the fusion method. Transmission electron microscopy images showed quantum dots in glass with an average size of 5.0 nm and interplanar distances of around d_{212}= 0.280 nm, which corresponds to the Bi_2S_3semiconductor. Energy dispersive X-ray spectroscopy analysis confirmed the chemical elements Bi, S and Co in the NCs. X-ray diffraction showed the peaks associated with the crystalline planes that are characteristic of the Bi_2S_3orthorhombic crystalline structure. The shift to greater angles of the (212) plane with increasing Co-content confirms doping in the orthorhombic unit cell. The changes in the optical absorption (OA) and photoluminescence (PL) spectra are strongly related to the tetrahedral (Th) symmetry of the Co^{2+}ions within the Bi_2S_3 NCs. The Racah and crystal field energy parameters confirm the symmetrical environment of the dopant ion. We clearly observe in the PL and OA spectra radiative and non-radiative IET from Bi_2S_3 NCs to Co^{2+} Th ion energy states. The valleys and peaks of the emission and absorption bands correspond exactly to the coordinate state of the $[CoS_4]^{6-}$ion. The PL and OA spectra reinforce the internal energy transfer process when analyzing the increased overlapping of the Bi_2S_3NCs' exciton bands and the decrease in stimulated emissions from Co transitions at Th sites [1].

In this work, the thermo-optical properties of gold and silver nanoparticles (AuNPs, AgNPs) obtained through green synthesis from Anacardium occidentale leaf extract were investigated. The studies of the non-linear optical properties of these nanostructures are important due to the localized surface plasmon resonance (SPRL) these materials are promising for several applications, such as photoconductors, photothermal therapies, biosensors, and optical limiters [1-3]. The nanoparticles were obtained through the reduction of silver and a gold solution, using leaf extract of the Anacardium occidentale (Cashew Tree), the samples were investigated by changing the concentrations of AgNPs and AuNPs. Through the absorption spectra obtained from the UV-VIS, we found the SPRL bands at 460 and 525 nm for AgNPs and AuNPs respectively, in which indicates the formation of nanoparticles. The SPRL peaks decrease linearly with the reduction of the nanoparticle concentration. With the Zeta potential analysis, we identified that the surface of the nanoparticles has a negative charge of -17 mV, indicating good stability. The nanoparticles had hydrodynamic diameters of 110 and 193 nm for AgNPs and AuNPs correspondingly. The thermo-optical properties were investigated using thermal lens spectroscopy, the AgNPs and AuNPs nanoparticles presented thermal diffusivities of the order of $8,71 \times 10^{-4} cm^2/s$ and $6,32 \times 10^{-4} cm^2/s$ respectively, the studies show that the propertiessuch as thermal diffusivity is sensitive to the change in intensity of the SPRL peak. Usingthe z-scan we identified that both AgNPs and AuNPs nanoparticles presented a non-linearthermal response, with a non-linear refractive index of around $10^{-3} cm^2/W$. Nevertheless, theresults indicate that AuNPs and AgNPs nanoparticles are promising materials for applications in photothermal therapy.

Investigation the optical and structural properties ofMn-doped Sb_2S_3 nanocrystals embedded in host glass

e-mail: edervgol@gmail.com

Dilute magnetic semiconductor (DMS) nanocrystals (NCs) xMn-doped Sb_2S_3embedded in host glass were synthesized by the fusion method. Transmission electron microscopy images show the formation of xMn-doped Sb_2S_3NCs with increasing size (2.1 to 3.8 nm) as a function of concentration (x = 0.00 to 0.40), respectively. Energy dispersive X-ray spectroscopy analyzes confirm the S, Sb and Mn precursor elements of DMS NCs. Atomic and magnetic force microscopy measurements show the magnetic contrast patterns resulting from the incorporation of Mn atoms into the structure of Sb_2S_3. The electronic paramagnetic resonance spectrum confirms the presence of Mn^{2+}ions ($3d^5$) located in the crystal field of the Sb_2S_3semiconductor due to six hyperfine transitions. The redshift of the Raman vibrational mode (^1A_g) with increasing xMn concentration gives strong evidence for the presence of Mn^{2+}ions in sulfur vacancies (VS) in the Sb_2S_3 unit cell. Optical absorption and photoluminescence (PL) spectroscopy measurements for xMn-doped Sb_2S_3NCs show the subtle tunable redshift of the band gap and excitonic recombination in the green-red region, with increasing x concentration. PL confirms that dopant Mn^{2+}ions fill V_{S2}that are dominantin Sb_2S_3. Therefore, the position of the energy states after the increasing concentration of Mn^{2+}dopant ions gives rise to a luminescence insight for a future scenario of research and applications involving sustainable DMS NCs [1].

A kind of glass that has drawn much attention in photonics is the photo-thermo-refractive (PTR) glass [1]. These are photosensitive materials that present changes in the refractive index after radiation and subsequent heat treatment, due to precipitation of nanocrystals in the glass matrix [2]. Normally, silicate glass is used, but its high vibrational energies limits its optical window in the infrared. An alternative to this problem is the use of compounds with lower phonon energy. Therefore, this work focused on the synthesis of a PTR glass with high LaF3 contents. To evaluate the influence of melting time and temperature on the samples, the melting of the composition 50GeO2-15K2O-35LaF3 was performed in three conditions: melting at 900°C for 1 hour and 1180°C for 30 minute melting at 900°C for 1 hour and 1180°C also for 1 hour; and melting of only the oxide for 6 hours at 1180°C and 1hour with the fluoride at the same temperature. No significant differences were noted in thethermal analysis, and the first condition was chosen. After the synthesis of glasses, thesamples were thermally analyzed by DSC and the presence of two crystallization peaks wasnoted in the nominal compositions 45GeO2-15K2O-40LaF3 and 45GeO2-10K2O-5NaF-40LaF3, being these samples the most promising for precipitation ofLaF3 nanocrystals. The next step consists of crystallization study by heat treatment. Silver will be used as the photosensitive agent for the growth of nanocrystals. Subsequently, thesamples will be irradiated with UV light, thermally treated and characterized in relation to the optical (UV-Visible and photoluminescence spectroscopy) and structural properties (XRD).

In several works related to the production of paper, plastic, cosmetics, food, and others, photocatalysts are used to degrade, catalyze, protect, clean, acidify and sterilize. A photocatalyst is an agent that can change the rate of a chemical reaction when exposed to light. Several materials have photocatalytic activity, and indeed, many more are to be discovered in the future. In this context, it is understood that it is essential to know the characteristics of a photocatalyst, mainly regarding its speed and efficiency in a chemical reaction. The general objective of this work is the development of low-cost, versatile, portable, and cloud-integrated equipment for determining the efficiency of photocatalysts using the principles of photodegradation of various dyes. This project offers an easy-to-replicate solution for universities. In addition, the aim is to increase the accuracy of the calculations performed to obtain the photocatalyst degradation yield since they usually are at most a dozen points in a photocatalyst characterization graph. Through the proposed solution, using measurements at small sampling intervals, e.g., on the order of seconds, procedures that usually last hours or even days can be characterized in an automated way, with low cost and greater precision. An application for data acquisition is developed and embedded in a microcontroller module, the ESP32 platform, which in turn is coupled to communication, measurement, and actuation devices, such as LEDs, light sensors (TEMT6000), and fluid pumps. Web and Mobile applications were developed for communication with the ESP32 module and for recording, viewing, and analyzing measurements.

Luminescence Concentration Quenching in Nitrogen-Doped Graphene Quantum Dots

Julia Beatriz Camargo Bachega[1], Davinson Mariano da Silva[2]

[1]Universidade Federal do ABC (*Programa de Pós Graduação em Ciências e Engenharia de Materiais*) , [2]Faculdade de Tecnologia de São Paulo (*Departamento de Ensino Geral*)

e-mail: juliabeatrizcb@gmail.com

The investigation of the luminescence mechanisms of carbon-based quantum dots has been a fruitful research subject in recent years [1,2]. However, even though the synthesis to obtain highly efficient graphene quantum dots (GQDs) with redshifted photoluminescence (PL) have been improved, few works have exploited the occurrence of luminescence concentration quenching (LCQ) in suspensions based in GQDs. This work aims to investigate the LCQ of graphene quantum dots doped with nitrogen (GQDN), synthetized from sucrose, in different solvents. The synthesis started with the carbonization of sucrose in sulfuric acid. Nitrogen doping was achieved by reflux in nitric acid. The resulting GQDN were dispersed in dimethylformamide (DMF), dimethyl sulfoxide (DMSO), isopropyl alcohol (C3H8O) and deionized water. GQDN dispersions in H2O and C3H8O presented PL in the blue region, when excited in the UV region (340-360 nm). On the other hand, GQDN dispersed in DMF and DMSO, showed a broad PL band (450-600 nm), when excited between 400 and 550 nm. The results also showed that in suspensions prepared with DMF and DMSO, LCQ occurred when GQDN concentrations exceeded 1.12 g/L and 2.65 g/L, respectively. In samples prepared in H2O and C3H8O, PL did not exhibit LCQ within the range of investigated concentrations. The results herein may be employed for the optimization of GQDN for applications in sensors, WLEDs, and random lasers.

Luminescent films containing rare earth fluoride nanoparticles for application in packaging and smart labels and waveguides

Ana Beatriz Acosta[1], Luiz Fernando dos Santos[1], Rogéria Rocha Gonçalves[2]

[1]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto da Universidade de São Paulo (*Departamento de Química*) , [2]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto da Universidade de São Paulo

e-mail: beatriz.acosta@usp.br

When doping systems with lanthanide ions, luminescent materials can be developed with interesting properties depending on their characteristics such as transparency at the excitation wavelength, the high solubility of lanthanide ions in the solid lattice, phonon energy, and chemical and thermal stability [1]. Our goal is the synthesis of redispersable luminescent Ln^{3+}-doped rare earth fluorides particles (Ln^{3+}= Eu^{3+}, Er^{3+}/$Yb^{3+}$and Tm^{3+}/Yb^{3+}) with controlled morphology and dimensions, and luminescent nanocomposite monoliths and films with potential application in photonics, as nanothermometers. Spectroscopic properties were studied, and up-converting luminescence was detected under excitation at 980 nm. In the emission spectra, bands are observed in the green (525 nm) and red (660 nm) regions, indicating that the materials have emissions in the yellowish-green region. The preparation of films is carried out from colloidal suspensions containing nanoparticles dispersed in the solvent and (bio)polymers, organic-inorganic and inorganic hybrid based on silica (by sol-gel methodology). The depositions are made on PLA filaments for 3D printing.

Alkali tantalum germanate glasses are interesting optical materials with high refractive index, high transparency in the middle infrared and are efficient hosts for rare earth luminescence [1,2]. These glasses are characterized by a limited Ta2O5 solubility in the germanate network and formation of tantalum rich regions in the glass structure built from interconnected TaO6 and TaO7 units. Hence, the glass forming domain in the ternary system (90-x)GeO2-10M2O-xTa2O5 (M being an alkaline ion) is limited from x=0 to x=20 mole%. Another interesting point is that transparent glass ceramics containing tantalate bronze-like structures (Na2Ta8O21) can be obtained from the most Ta2O5 concentrated samples. Such Er3+-doped glasses and glass-ceramics exhibit improved luminescent properties in the infrared and tunable red and green upconversion emission depending of the composition and crystallization state. The detailed crystallization mechanisms were investigated in these glasses and it appeared that short heat-treatment times around the onset of crystallization promote the volume precipitation of perovskite Na2Ta8O21 whereas longer heat-treatments induce the formation of surface spherulites associated with the crystallization of quartz-like α-GeO2. This latter phase is associated with a strong SHG (Second Harmonic Generation) signal generated from the spherulites. Another efficient way of promoting SHG in these glasses is the thermal poling under high DC voltage, with the sodium depleted layer and related static electric field responsible for a strong SHG signal associated with EFISH mechanisms. The use of microstructured electrodes also appeared to be suitable for the microimprinting of optical patterns with microscaled controlled linear and non linear optical properties and topology.

Luminescent thin films based on Er³⁺-doped germane-tellurite nanoglasses

e-mail: jchacaliaza@usp.br

In this work, thin films were fabricated by spin-coating at different speeds and their properties were studied using characterization techniques such as luminescence under 980 nm excitation, AFM thickness and texture measurements, and Raman spectroscopy. The first step was to nanostructure Er^{3+}-doped germane-tellurite glasses (the set of glasses has the chemical composition: 59.95% TeO_2- 20% ZnO - 10% GeO_2- 10% Na_2O - 0.5% Er_2O_3). Afterward, mix the nanoparticles with anisole (solvent) and finally with Polymethylmethacrylate (photoresist). Finally, the mixture was deposited on pure Si substrates using the spin-coating technique, where the influence of rotation speed on the thickness of the thin film was analyzed [1]. The results obtained revealed that the spin-coating speed influences the texture and thickness of the films, which in turn affects the optical and structural properties of the materials. Furthermore, strong light emission in the green region was observed in our thin films, suggesting its possible application in photonic devices and offering novel insight into the synthesis and characterization of thin films by spin-coating [2].

e-mail: laskowski@alunos.utfpr.edu.br

Magneto-plasmonics (MP) refers to multifunctional nanomaterials that simultaneously exhibit plasmonic and magnetic phenomena. This blending of magnetism and photonics at the nanoscale is generally achieved by combining plasmonic materials such as Au and Ag with magnetic materials such as 3d metals and their oxides [1]. In this work, we present experimental results on the laser ablation synthesis in solution (LASiS) of Au-Fe (oxide) core-shell nanoparticles (NP) in water. Our methodology consists of two steps: first, a gold target is irradiated with 1064 nm (400 ns; 0.5 mJ) pulses from a fiber laser at 50 kHz, leading to pure Au second, a glass vessel filled with the Au NP colloidal solution prepared in the first step is further used for the laser ablation of an iron target. Different LASiS setups were tested, with varying Au and Fe target-ablation time therefore, optimal Au and Fe colloidal concentrations were determined to synthe very stable hybrid Au-Fe (oxide) nanoparticle solutions. NP characterization via UV-Vis spectrometry shows a surface plasmon band centered at 530 nm, which accounts for the solution's vivid purple color; in addition, DLS and TEM reveal spherical NP with an average of 10 nm. NP structure characterization through EDS and XPS indicate the presence of iron oxide, which explains why a small neodymium magnet placed at the bottom of a test tube filled with the colloidal solution can attract all the NP to the bottom in less than 5 minutes. These core-shell Au-Fe (oxide) NP are promising materials for biophotonic applications, including bioseparation, in vivo imaging, and sensing. As a proof-of-concept test, we successfully used our Au-Fe (oxide) NP as substrates in Surface Enhanced Raman Spectroscopy (SERS) experiments to detect minute amounts of biological molecules such as amino acids and urea in aqueous solutions.

e-mail: eloisa.hilario@usp.br

In the anti-Stokes excitation of trivalent rare-earth ions, the excitation photons energy is smaller than that of a given absorption transition, and the energy mismatch can becompensated by annihilation of phonons from the host lattice. Since the occupation number of phonons increases with the temperature, heating the system generally increases the efficiency of anti-Stokes excitation. Here, we exploited an intrinsic heating associated withlight-to-heat conversion in the interaction of a laser light with metallic nanoparticles (Ag or Au) on the surface of $Nd_xY_{1.00-x}Al_3(BO_3)_4$(x= 0.10, 0.20, and 1.00) sub-micrometric particles to enhance the anti-Stokes excitation efficiency with light at 1064 nm. Several upconversion emissions are observed from 600 nm to 880 nm, with the more intense at 750 nm due to the Nd^{3+}transition $\{^4F_{7/2}, ^4S_{3/2}\} \rightarrow {}^4I_{9/2}$. 300-fold enhancements are demonstrated for silver (Ag) nanoparticles, when compared with the pristine $Nd_xY_{1.00-x}Al_3(BO_3)_4$particles.

e-mail: anacardoso.2000@alunos.utfpr.edu.br

The great interest of nanomaterials (NMs) is due to their different and modulated properties comparing to those of their bulk solids [1]. The class of metal nanoparticles (NPs) stands out because of their properties such as high chemical stability and high catalytic activity, as well as interesting optical properties resulting from surface plasmon resonance (SPR) [2,3]. Based on this, the present work aims to the synthesis and characterization of bimetallic and monometallic NPs of copper (Cu) and platinum (Pt) films, deposited on silica substrate. For the synthesis, silica coverslips were treated by piranha solution (2:1 H2SO4/H2O2), followed by the functionalization with 3-aminopropyltriethoxysilane (APTES) (10% v/v) simultaneously with the deposition of metallic precursors, in toluene solution and, finally, by the thermal reduction step at 300°C for a period of 15 minutes in a muffle furnace. Bimetallic films presented visually greater uniformity compared to monometallic Cu films, demonstrating the influence of Pt on the quality of synthesized films. The samples were characterized by UV-Vis spectroscopy, where the plasmon absorption signal was observed for all samples containing Cu. With the transmission electron microscopy (TEM) images, it was possible to observe the formation of a bimodal distribution of the NPs, whose crystallinity was observed by dark-field images, as well as the formation of organized 2D carbon structures, like graphene, resulting from the APTES pyrolysis. DRX, SEM and Raman measurements, in progress, will allow analyzing the crystallinity, homogeneity, composition and stability of the synthesized films.

Modulating white light emission temperature in $Ho^{3+}/Yb^{3+}/Tm^{3+}$ triply doped GeO_2-Nb_2O_5 materials for lighting applications

Vítor dos Santos de Souza[1], Fábio José Caixeta[2], Karmel de Oliveira Lima[1], Rogéria Rocha Gonçalves[1]

[1]Universidade de São Paulo (*Química*) , [2]Universidade Estadual Paulista / Instituto deQuímica (*Química*)

e-mail: vitor_santos_souza@outlook.com

Materials based on 0.3% Ho^{3+}/1.2% Yb^{3+}/0.5% Tm^{3+} triply doped with GeO_2–Nb_2O_5 were prepared by the sol gel methodology followed by thermal annealing at temperatures ranging from 700 to 1100 °C, which affected the structure and the white light generation of the solids. The spectroscopic properties of the samples depended on the final structure. In the photoluminescence spectra under ultraviolet excitation, it is possible to observe a characteristic broad band from 360 nm to approximately 600 nm, which overlapped some transitions of rare earth ions depending on the thermal treatment. This broad band was attributed to the emission of the GeO_2-Nb_2O_5 host lattice. In addition to the emission band of the host lattice, the emissions of the Ho^{3+} ions at 540, 590, 613, 623, and 653 nm were observed. The emissions of the Tm3+ ions at 653 and 704 nm transitions. The sample treated at 1100 ºC stood out: it generated white light through modulation of the warm white illumination under excitation at longer ultraviolet wavelengths (275 and 280 nm) and cold white under excitation at shorter ultraviolet wavelengths (245 to 270 nm). In this sense, changes in the excitation wavelength can generate the quality of white light that is necessary for a given lighting environment.[1]

In this work the nonlinear optical properties of a phosphate glass matrix doped with $Nd^{3+}$and codoped with CdS nanocrystals have been investigated by the time-resolved Z-scan technique[1]. Analyzing the transient signal, we show that it was possible to discriminate the thermal effect from the populational effects on the nonlinear refraction and absorption, allowing the determination of the parameters n_2', n_2'' and n_4'. We also investigated the dependence of these parameters on the relative concentration of Nd and CdS, and we observed a linear increase of these parameters with the CdS absorption. Evidence of energy transfer between Nd and CdS nanocrystals[2] was investigated by the determination of the non-radiative decay rate through lifetime measurements monitoring the emission at 1064 nm referring to the transition $^4F_{3/2}$□ $^4I_{11/2}$ of the Nd^{3+}. For this work, carbon dots were synthed by the hydrothermal method using biomass from the mesocarp of the Orbignya speciosa plant (babassu coconut) as a precursor, following a route proposed by Costa and colleagues [1]. The formation of the desired material was confirmed by UV-vis, FTIR, and Fluorescence, which indicated the formation of carbon dots, the presence of various functional groups on the surface, and their photoluminescence. The properties and stability of the material were characterized by TEM, DLS, and Zeta potential, which showed that the samples had an average diameter of approximately 63 nm and a Zeta potential of -34 mV. Recently, the optical nonlinearity properties of carbon dots have been highlighted, so Z-scan and thermal lens spectroscopy measurements were performed to extract the nonlinear optical (n2) and thermo-optical parameters. The carbon dots showed a nonlinear response ranging from -5.6×10-12 cm2/W to -6.4×10-12, obtained by fitting the experimental data using the standard model proposed by Cuppo and colleagues [2]. The thermal diffusivity values obtained were approximately 1.4×10-3 cm2/s, indicating the potential of the material for photonics applications and thermal insulation.

e-mail: alexandre.camara@uerj.br

This work presents the optical properties of a simple, but interesting organic salt. The crystals were built up from 2-aminopyrazine as a cation, with N1 protonation and dihydrogen phosphate as anion [1]. The crystals exhibit a second-order optical nonlinearity and could therefore be useful for photonic applications. This response occurs due to the dipole formed by the interaction of aminopyrazine and phosphoric acid, a system resembling the renowned KDP crystal. As a consequence, it was possible to measure a non-centrosymmetric phase showing second harmonic generation in powder formed from microcrystalites of the new material. The nonlinear optical characterization was performed in two experiments. Firstly, the powder was exposed to optical trains of Q-switched mode-locked pulses of varying intensity from a Nd:YAG infrared laser (1064 nm, 900 mW). The SHG light was detected by a photomultiplier in reflection and in transmission through the sample. The FWHM of the green pulse train was ~1.33 shorter than that of the IR pulses, a value close to the theoretical value ($2^{0.5}$) expected for frequency doubling. Also, the polarization of the incident light was changed 360° in steps of 5° and the SH intensity was monitored. A large angular dependence of the SHG light intensity on this parameter was observed, with the ratio Imax/Imin approaching ~9 for one polarization angle.

Niobium has been considered a promising material for science due to the good results indicated in current studies. For Brazil, expanding knowledge and applicability of Niobium (Nb) is of great importance since the country is the largest holder of the ore in the world, around 98%. Copper niobate ($CuNb_2O_6$), in turn, is one of those Nb compounds that are gaining prominence in science because its properties enable its application in technological sectors. The process of obtaining $CuNb_2O_6$can result in different phases and properties, so in this study, therefore, nanoparticles of $CuNb_2O_6$were produced using the proteic Sol-Gel synthesis route modified with gelatin from the precursors Niobium Pentoxide and Oxide of copper. After synthesis, the powders were calcined in a muffle furnace at temperatures of 800 °C, 900 °C and 1000 °C, for 3 h and a heating rate of 5 °C/min. Subsequently, they were characterized using X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM), Energy Dispersive Spectroscopy (EDS) and Raman Spectroscopy. XRD results show that, at 800 °C, the monoclinic phase of CuNb2O6 is identified, however, this was only completely obtainedwhen calcined at 900 °C. The samples calcined at 1000 °C resulted in the complete orthorhombic phase. All samples with total formation of polymorphs showed good dispersivity, with no evidence of contamination, the morphologies of the characteristic particles and the Raman spectra were consistent with the literature.

Inorganic nanocrystals (NCs) of various compositions have become an increasingly studied research topic in recent years with special attention given to lanthanide compounds. Their luminescence properties can be tailored for several applications like solar cells, photocatalysis, in vitro and in vivo biological markers, etc. Accurate determination of their internal structure and chemical composition is fundamental to the understanding and development of new nanomaterials. It has been demonstrated that the growth of a shell surrounding the core nanoparticle is a common way to improve the luminescence efficiency of such materials. This design introduces the possibility of constructing novel upconversion nanoparticles. The luminescent mechanisms of lanthanide ions can be divided into two categories: energy upconversion (UC) and energy downconversion (DC). Lanthanide upconversion luminescence is an anti-Stokes shift process where lanthanide ions absorb lower energy photons and emit higher energy photons. In this study, core and core-shell-structured lanthanide-based nanocrystals with energy upconversion properties were synthed by traditional high-temperature thermolysis using oleic acid, octadecene, and lanthanide salts as precursors. The NaGdF4 matrix was used to form NaGdF4:Yb3+,Er3+ core-only, and NaGdF4:Yb3+,Er3+@NaGdF4 core-shell nanoparticles with hexagonal (β phase) crystal structure as confirmed by XRD diffraction. Optical properties were studied by UV-Vis and photoluminescence spectroscopy. The upconversion mechanism is due to energy transfer from Yb3+ to Er3+ while the passivation of surface defects on the core by the shell increases the luminescence efficiency. In these materials, green (540 nm, 4S3/2 → 4I15/2 transition) and red (650 nm, 4F9/2 → 4I15/2 transition) emissions were detected upon excitation at 976 nm (2F7/2 → 2F5/2 transition of Yb3+).

Optical properties of silver indium sulfide quantumdots coated with cadmium chalcogenides

I-III-VI ternary quantum dots have optical and electronic properties modulated through chemical composition and scale. The production of heterojunctions improves the optical properties of nanosystems, being the formation of core/shell systems the most suitable for nanocrystals of this type. [1] In this work we report the modulation of optical properties of AIn_5S_8(AIS) nanocrystals when coated with CdX seeds (X: S^{2-}, Se^{2-}). The synthesis were performed in electrochemical cavity cell, and stabilized by L-glutathione. The formation of the AIS/CdX heterojunction was carried out so that the core/shell ratio, with respect to the chalcogenides, was 1:0.25, 1:0.5, 1:1, or 1:1.5. After the formation of AIS/CdX, a hypsochromic shift was observed in the emission spectra for the AIS/CdS systems ($\lambda_{em}$from 585 nm to 571 nm) and bathochromic for the AIS/CdSe systems (λem from 585 nm to 560 nm). The AIS QDs obtained quantum yield (QY%, R6G pattern) equal to 4.06%. After CdS and CdSe coatings, the QY ranged from 9.36% - 11.6% and 2.70% - 0.78%, respectively. X-ray diffractograms presented the cubic structure formation of AgIn5S8, and after the coverage was verified the displacement of the diffraction peaks to lower 2θ values when coated with CdS, and to high 2θ values when coated with CdSe. The structural evolution is associated with the difference between the ionic radii of $Se^{2-}$and S^{2-}. In the time-resolved photoluminescence experiments, AIS showed a strong dependence on electronic defects, with 97.01% of relative abundance its associated with donor and acceptor states (DAP). The average lifetime increases when in the presence of coatings, due to the increase in lifetimes associated with processes mediated by defects. The presented properties demonstrate the potential of coatings in modulating the optical properties of semiconductor nanocrystals, which can be enhanced as in this work in the presence of CdS.

e-mail: pedrozaramella.pz@gmail.com

Curcumin has, recently, drawn attention and attracted research investments around the world due to it abundant properties in both optical and biological science. Some of its biological applications in traditional and modern medicine involves antitumor, antioxidant, antiviral and anti-inflammatory properties and can even be used in cases of Alzheimer’s, psoriasis and diseases of the digestive system. The effects of curcumin are directly connected with its form of administration, however, its low solubility in water results in low bioavailability, as it is poorly absorbed by the body in the most common forms available. A possible solution is the production of stable complexes formed by curcumin and metals such as magnesium (Mn), iron (Fe), copper(Co), zinc (Zn) among others from groups 7-12 of the periodic table. In addition, to increase its bioavailability, these complexes allow diverse biotechnological applications from medicines to sensors. The materials chosen for this study are complexes constituted by curcumin and a metal and, for the optical characterization of the complexes, we used optical techniques such as photoluminescence, ellipsometry, Raman. Chemical techniques were used for a better structural understanding, such as magnetic resonance. Some optical characterization exploring a possible magnetic circular dichroism and other effects involving magnetic field, were also be performed. The low number of studies that explore this type of complex, in terms of the radiation interaction with matter, turn this study essential to understand its mechanisms and may shed new light onthe exploration of curcumin, within the applications mentioned in the text

Optical thermometry of tellurite glasses doped withEr^{3+}-Yb^{3+} under UV and NIR excitation

Gaston Lozano Calderón[1,2], Victor Anthony Garcia Rivera[2], Younes Messaddeq[2], Euclydes Marega Junior[1]

[1]Instituto de Física de São Carlos - USP, [2]Centre d' optique, Photonique et Laser - Université Laval

e-mail: glozano@usp.br

The use of glasses doped with rare earth ions (REI) as optical sensors have a high potential to be implemented as optical fibers. Tellurite glasses offer excellent optical, thermal, and structural properties in this scenario. The ability to incorporate large amounts of REI is a notable candidate for these purposes. One of the most used techniques for optical thermometry is the fluorescence intensity ratio (FIR). The main advantage of using this technique is that it is not affected by external factors such as energy fluctuations of the excitation sources [1]. In this research, tellurite glasses doped with Er^{3+}-Yb^{3+}were fabricated to study their thermal sensing performance under 380 and 980 nm excitation. The FIR was applied on the 2H11/2 and 4S3/2 thermally coupled levels of the Er3+ in the temperature range of 93 - 348 K. These glasses exhibit high thermal sensitivities, and their values depend on the REI concentration and excitation source. Furthermore, the refractive indices (>2.04 at 532 nm) and thermal stability are higher compared with other Er3+-Yb3+ doped tellurite glasses for thermal sensing applications. These features become our glasses propitious candidates for optical fiber, luminescent material, and thermal sensing.

Laser processing of glasses have been widely used to promote local changes on material properties and structure, promoting applications from photonic devices to microfluidics. Advances on laser technology have expand the glass processing possibilities, enabling to achieve 3D manufacturing, bulk or surface crystallization. Moreover, laser-induced crystallization is relevant to functionalize glass matrices through the precipitation of different micro/nanocrystals, such as $LiNbO_3$and β- $BaB_2O_4$with second harmonic generation [1]. Concerning the nonlinear optical properties, it is also important to search for materials with significant third-order susceptibility, in which heavy-metal oxide glasses have excelled due to their hyperpolarizabilities. Previous results on 50-BO1.5-50PbO glass showed that fs-laser associated with chemical etching in KOH solution resulted in the architecture of lead oxide microcrystals [2]. In order to determine the influence of pulse duration on the crystallization process, we used a ns-laser to irradiate the 50-BO1.5-50PbO glass. Laser pulses of 10 ns at 1064 nm, with repetition rate of 10 Hz were focused on the glass surface, which was translated regarding the beam at constant scan speeds of 0.2-7 mm/s. Results shown that independent of scan speed, the bottom surface became crystalline, which has been discussed to be due to self-focusing effect associated with the high nonlinear refractive index of the glass (n_2= 4.7 x $10^{-19}m^2/W$ at this wavelength). The formation of metallic lead (Pb) was identified by x-ray diffraction, being responsible for changes the crystallization process in KOH solution previously investigated. e-mail: mercia.sfreire@ufpe.br

Quantum dots (QDs) are semiconductor nanocrystals with sizes ranging from 2 to 10 nm, which have charge carriers (electrons and holes) in a quantum confinement regime, giving them optical properties, that can be modified just by varying their size or chemical composition. Furthermore, QDs exhibit high photostability, having resistance to photobleaching over a period of minutes to several hours, and have a chemically active surface that can be conjugated to molecules of interest, increasing their affinity with the analyte. Due to their properties, QDs have been used for a wide range of applications, like sensors, cellular markers, and solar cells. [1,2]. On the other hand, the most established QDs in the literature are prepared in organic solvents and with harsh conditions, and/or have high toxicity due to the presence of heavy metals in their constitution, such as lead and cadmium, which lower their potential for the majority of applications. In this context, ternary QDs like silver and indium chalcogenides, appear as a solution, since they possess excellent fluorescence and very low toxicity. Thus, this work had the aim of developing a synthetic procedure to prepare AgInTe2 in an aqueous medium. For this, a chemometric study was carried out, varying temperature, pH, synthesis time, and precursor concentration, in order to optimize the optical properties of the AgInTe2 QDs. From the optical characterizations, promising results were found in relation to the fluorescence intensity, allowing the produced material to be used, among other applications, as an optical sensor.

This work aims to study the synthesis and structural and optical properties of a vitreous system formed by B_2O_3, TeO_2 and SrO. The samples were synthesized by melt-quenching method with the following composition (X)SrO-(Y)B_2O_3-(Z)TeO_2 where X=10, 16, 26 and 30; Y=20, 29, 44 and 50; Z=70, 55, 30 and 20wt%, respectively. The glass samples were characterized by X-ray diffraction, Raman spectroscopy, optical absorption spectroscopy, volumetric density, and refractive index. A ternary phase diagram of the synthesized samples was elaborated. The results obtained were discussed from the concentration of TeO_2 of the glasses. From the analysis of X-ray diffraction it was possible to confirm the amorphous character of the samples [1]. Raman spectra present bands associated to BO_3, BO_4, TeO_3, TeO_{3+1} and TeO_4 units. The optical absorption spectra have a wide optical transmission window in the range of ~590 nm to 2050 nm. Refractive index and volumetric density values increase linearly as a function of the increase of the TeO_2 concentration, which occurs due to substitution of B_2O_3 and SrO by TeO_2. The results suggest that these glasses are excellent candidates for rare-earth doping and optical applications [2].

Sulfones are a group of compounds of pharmacological interest and are produced by Friedel-Crafts sulfonylation of arenes. Photocatalysts, as quantum dots (QDs) gain relevance for their efficiency and degree of recovery. This work presents the combined effect of the chemistry of surface defects on cadmium selenide QDs (CdSe QDs) and their impact on photocatalyst performance for sulfonylation reactions. Cysteamine-stabilized CdSe QDs were electrosynthed and the combined effect of surface defect and chemistry was controlled for time of heat treatment under reflux (t = 0.5, 1, 2, and 4 h). The reaction between benzyl bromide and sodium p-toluenesulfinate, photocatalyzed (365nm, 6W) by CdSe QDs, was used as a reaction model.[1] CdSe QDs showed a progressive decrease in optical bandgap from 2.45 eV (0.5 h) to 2.30 eV (4 h). At the same time, the combined effect of increasing the full width at half maximum (FWHM) of the emission band and the emission wavelength (λem) from 120nm/631nm (0.5 h) to 126nm/650nm (4 h) was verified, which are associatedto the rise of surface defects, particle growth and Stokes shift. Thus, the heating time leadsto a decrease in the quantum yield, in addition to the increase of the luminescence half-lifetime. The light-off sulfonylation reaction in presence of CdSe QDs led to 12% yield of benzyl-p-toluenesulfone (2 hs reaction time). Under UV light (365 nm), the photocatalysis yields decreased from 99% to 92%, according to the increasing of CdSe nanoparticle and decrease of quantum yield. CdSe intragap recombinations diminish the transfer of electrons on the QD surface, thus decreasing the efficiency of the photocatalytic reactions, which is a proof-of-concept of the influence of the surface defects on sulfonylation reactions photocatalyzedby QDs.

The interesting physical and chemical properties displayed by nanomaterials have provided an increase in their applications in various fields of science and hence an increase in the search of synthesis routes favoring a greater control of size and shape of the nanoparticles. Among the various available routes of synthesis, the photoinduction has been disclosed as simple and powerful technique, allowing to obtain monodisperse nanoparticles. Spatial self-phase modulation (SSPM) is a phenomenon characterized by the appearance of diffraction rings in the far field when a Gaussian profile laser focuses on a non-linear medium. By relating the number of rings formed with respect to a given power of the excitation laser, it is possible to determine the module of the so-called non-linear refractive index n2 of the sample. The sign of n2 can be determined from the laser-induced thermal lens. The modification of the laser wavefront causes it to undergo convergence or divergence, depending on whether the refractive index of the medium is positive or negative, respectively, which is related to n2. The emergence of rings is due to the phase variation $\Delta\varphi NL$ acquired when passing through the medium. The technique is very sensitive with dilute samples, which makes it an excellent spectroscopic tool for characterizing liquid samples. Although SSPM has been developed as a typical method for nonlinear optical response, the origin of the change in refractive index due to the phenomenon is still little explored. In this work we present the photothermal characterization through the spatial selfphase modulation technique of gold nanoparticles (AuNPs) obtained through the photochemical reduction of the precursors dispersed in water. Particle size and shape influence the optical response of the fluid, facilitating or hindering the appearance of diffraction rings due to laser excitation.

Spectroscopic properties investigation of MnO doped alkaline borate glass

Natacya Fontes Dantas[1], Taís Silva Morais[1], Franciana Pedrochi[1], Alysson Steimacher[1]

[1]Universidade Federal do Maranhão (*CCIm*)

e-mail: natacya_dantas@hotmail.com

Glasses doped with transition metal (TM) ions have been widely investigated because of their interesting spectroscopic and optical properties, which make them favorable candidates for application in the fields of opto-electrical and electrochemical devices. Among TM ions, manganese is attractive since it exhibits different valance states depending on the properties of the glass matrices [1,2]. In this work, an alkaline borate glass was doped with different concentrations of MnO (0.05, 0.10, 0.25 and 0.50 %mol) to evaluate the spectroscopic properties as a function of the dopant concentration. The samples were prepared by the traditional melt-quenching method in air atmosphere and their properties were investigated by DRX, FTIR, optical absorption, excitation and luminescence spectra, and CIE chromaticity diagram. The absorption spectra present characteristic transitions of $Mn^{2+}$and Mn^{3+}ions, and the bands in the luminescence spectra change as a function of the excitation source. The results are promising for the material application on technological devices.

Materials science has experienced important advances in recent years, notably, many works are directed for materials with applications aimed at visible light sources [1]. The Tm^{3+}can have a strong blue emission, which allows the development of lasers and LEDs in this color region which makes it possible to use this element in glass matrices aimed at photonic applications [2]. This study refers to the synthesis of a vitreous series in oxyfluorides phosphate system, (38)P_2O_5-50-xKF-12Al_2O_3-xTm_2O_3(PKAl:Tm), with x= 0.25, 0.50, 0.75 and 1 mol%, by the melt-quenching method. The synthesized materials showed amorphous characteristic verified by XRD data. The absorption spectra show six main bands characteristic of Tm^{3+}ions, from ground state $^3H_6$to excited levels $^3F_4$, $^3H_4$, $^3H_5$, $^3F_{3,2}$, $^1G_4$and $^1D_2$, which shows an intensity increase with the concentration. In the FTIR spectra, it was verified that the profiles of the PKAl samples are similar to glasses based on phosphate systems. The excitation spectra of PKAl:Tm glasses show an intense band centered at 358 nm ($^3H_6 \rightarrow {}^1D_2$). The luminescence spectra with excitation of 358 nm show three bands at 453 nm ($^1D_2 \rightarrow {}^3F_4$), 480 nm ($^1G_4 \rightarrow {}^3H_6$) and 660 nm ($^4F_{9/2} \rightarrow {}^6H_{11/2}$); the highest emission intensity was observed to the sample doped with 0.75 mol% of Te2O3. The calculated CIE diagram shows that the doped samples have coordinates close to the primary blue color, which favors the application for the development of blue LEDs and wLEDs. These results show that the PKAl:Tm glasses are a good candidate for optical and photonic applications.

e-mail: marianapassarin@gmail.com

Hybrid nanocomposites formed by a polymeric matrix and metallic nanoparticles are a class of materials that have received great interest for optical sensors, electronic devices, and biomarker nanosensors. In this study, we report the synthesis and characterization of luminescent nanocomposites based on gold nanoparticles (AuNPs) anchored or adsorbed to the luminescent complex $[Eu(tta)_3(H_2O)_2]$, where tta = thenoyltrifluoracetone, in the presence of the polymer polypyrrole (Ppy), seeking synergism between the phases and improvement of properties compared to isolated chemical components, for sensing applications and to perform electronic devices based on optical fiber. The nanocomposites were synthed by varying the amount of monomer pyrrole, gold precursor $HAuCl_4$and europium complex. The AuNPs plasmon band was identified by UV-Vis spectroscopy, and absorption bands from the tta ligand and Ppy polymer also confirm hybrid formation. The AuNPs were identified by TEM results, where crystalline structures were observed in dark field images for all samples. Moreover, this technique provided evidence of the polymer acting as a stabilizer. Photoluminescence spectra displayed intra-configurational transitions of the Eu^{3+} ion observed for all sample conditions, except for those where a higher amount of pyrrole was added in the synthesis (36 μL of pyrrole 5.0×10^{-2}mol L^{-1}), explained as a result of quenching mechanisms. Confocal optical microscopy images from hybrid nanocomposite evidence europium complex presence. Furthermore, AFM images suggest that the presence of the complex promotes changes to the sample's surface, making it rougher and thicker.

The study of metal nanoparticles is of great interest both scientifically and technologically due to their unique properties related to Localized Surface Plasmon. Therefore, precise control over the shape and size of nanoparticles is necessary, which requires special attention during synthesis. In this study, the synthesis of silver nanoparticles was investigated through the photochemical method, in which photons are absorbed by a photochemically active compound, inducing the reduction of metal ions. To obtain silver nanoparticles, a solution of 1 mMol of $AgNO3$, sodium citrate and PVP were used, and the solution was exposed to the light of a LED. Some parameters were changed in different syntheses, such as the wavelength of the LED, the quantity of sodium citrate and PVP, and the exposure time to the LED light. After synthesis, UV-visible spectrometry was performed to observe the formation of nanoparticles, dynamic light scattering (DLS) to observe the size of nanoparticles, and Zeta potential measurement to verify the stability of nanoparticles. It was observed that increasing the quantity of sodium citrate led to a decrease in the absorption peak in UV-visible spectrometry and an increase in the mean size of nanoparticles. The same effect was observed with an increase in PVP. With variation in the wavelengths of the LEDs, the samples made with the UV LED showed a much higher absorption peak in UV-Vis spectrometry than the samples made with other wavelengths.

STUDY OF THE SYNTHESIS AND CHARACTERIZATION OF COPPER NIOBATE VIA THE SOL-GEL METHOD FROM THE PREPARATION OF THE NIOBIUM PRECURSOR

This work aims to study the synthesis of Copper Niobate (CuNb2O6) via the proteic Sol-Gel method, which is a wet chemical route little used for the preparation of this material, but stands out for being a green synthesis, starting from the preparation of the Niobium Ammonium Oxalate precursor. Niobate has stood out in science due to its various properties and technological applications, such as in solar cell devices, microwaves and infrared lasers. Therefore, the need to produce this nanomaterial with a simpler and low-cost methodology became greater. For this, Niobium Ammonium Oxalate precursor powders were used, prepared from melting and complexation processes, and commercial Copper Nitrate, both of which have high solubility in water, in addition to the addition of agar-agar as a chelating and polymerizing agent. . After obtaining the gels, the powders received the appropriate thermal treatment, were calcined in a muffle at temperatures of 700 °C, 800 °C, 900 °C and1000 °C, for 3 hours at a heating rate of 5 °C /min. Subsequently, the obtained powders were characterized by RAMAN Spectroscopy, X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM) and Energy Dispersive Chemical Microanalysis (EDS). so it was found that for the calcined niobate at 900 °C complete formation of the product in the monoclinic phase occurred, and at 1000 °C CuNb2O6 formed completely in the orthorhombic phase. These samples with complete formation of the compound showed good results, such as good dispersion, high purity, no evidence of contamination and characteristic morphologies, consistent with the literature.

Substrate type influence on indium oxide films,obtained from resistively evaporated indium.

Renato Dias de Souza[1], Lucas Prado Fonseca[2], Luis Vicente de Andrade Scalvi[1,3]

e-mail: renato.dias.desouza@hotmail.com

Indium oxide (In2O3) in stoichiometric form is an insulator, whereas in the non-stoichiometric form it behaves as a wide bandgap semiconductor (>3eV), with high transparency in the visible and high reflectivity in the infrared. These properties lead to an expressive applicability [1]. Nanomaterials based on In2O3 have received considerable attention for technological applications [2], such as thin film transistors (TFT) [3], transparent conductors and ultraviolet sensors, among others.The main parameters considered are the substrate type for film deposition: silica or soda-lime glass, along with the thickness of the In film, deposited by resistive evaporation. To obtain In2O3, In filmswere kept at a temperature of 300°C for 2.5h (under room atmosphere conditions), which isreached at a rate of 1°C/min starting from room temperature. Measurements of X-ray diffraction (XRD) allow verifying that films 200nm thick present characteristic planes of twostructures: from the originally deposited metallic Indium and from In2O3, forming a nanocomposite of both structures. For 50nm and 100nm thick films, XRD data reveals onlythe formation of In2O3, differing in the intensity of the existing peaks. For more uniformoxidation, diffusion throughout the film should be made possible, where the oxygen atoms would need larger energy, or more time. Films deposited on soda-lime glass have bettercrystallization than films deposited on silica. One of the main causes of this observation maybe related to the difference in roughness of the used substrates. Soda-lime glass has an average roughness higher than silica. The increase in roughness directly affects the increase in surface area, increasing the availability for oxygen atoms to adsorb on the surface, originating the oxidation of the In layer to In2O3.References[1] G. Polymers based on vegetable oils can be excellent suitable candidates for replacing fossil polymers, for example, polyurethanes (PU) based on castor oil (CO). However, the synthesis of PU materials is normally carried out using organic solvents, metals and high temperature[1]. To overcome these problems, the sol-gel route is an alternative approach based on mild conditions to produce environmentally friendly organic-inorganic hybrid urethanesil (Ut) [1]. Therefore, in this study, we proposed the synthesis of a sustainable organic-inorganic hybrid (OIH) based on Ut derived from CO, as well as the incorporation and interaction of europium β-diketone $[Eu(tta)_3(H_2O)_2]$ and UCMPs NaF_4 : Yb/Er[3]. Ut hybrid was synthesized from the reaction of 3-(triethoxysilyl)propyl isocyanate (ICPTES) and CO in a 3:1 molar ratio. The films were obtained by the sol-gel process, following the casting method[1]. The CO-based OIH films showed high transmittance in the visible and infrared (90%), without major changes with the insertion of dopants and the Ut matrix. The results also revealed an increase in the intrinsic quantum yield of PL (Q^{Eu}_{L}) for $[Eu(tta)_3(H_2O)_2]$. Is has been verified a value of 27% for the isolated complex, while when it is incorporated into OIH PU a value of 49% was observed[2]. In addition, the UCMPs of 8 um was successfully doped, as observed by UC luminescence results.

SYNTHESIS AND CHARACTERIZATION NON-LINEAR OPTICAL OF BIMETALLIC SILVER AND GOLD NANOPARTICLES BIOSSYNTHESIZED FROM HYMENAEA COURBARIL (JATOBÁ)

e-mail: tania.patricia@ufpi.edu.br

Green synthesis has been considered an innovative and sustainable alternative for producing metallic nanoparticles (NPMs) due to the use of phytochemical compounds or their parts as reducing agents and stabilizers [1, 2, 3]. This study reports, for the first time, the use of an aqueous extract of Hymenaea courbaril (Jatobá) as a reducing agent and stabilizer in the synthesis of metallic gold (AuNPs), silver (AgNPs), and bimetallic (Ag@AuNPs) nanoparticles, and investigates their non-linear optical properties with continuous laser excitation. The presence of Localized Surface Plasmon Resonance (LSPR) bands confirmed the formation of metallic nanoparticles that are characteristic of these nanomaterials. DLS measurements revealed varied s and polydispersity of the nanoparticles, and all nanostructures have a negative surface charge. TEM images showed that the nanoparticles have a spherical shape. Thermo-optical properties were investigated using thermal spectroscopy techniques, which showed thermal diffusivity values of the order between (8-10) x10-4 cm²/s. The Z-scan Technique demonstrated that the non-linear refractive index is negative. The non-linear effects of the nanostructures indicate that they can be controlled depending on the composition of the nanostructure. The results indicate that nanoparticles can be applied in systems for optical limitation, studies in non-linear optics, and Photothermal Therapy.

The growing need for energy generation using renewable resources has motivated research at a global level. Energy conversion using non-renewable sources (fossil fuels) has contributed, on a large scale, to air emissions and other environmental risks over the years. One of the alternatives for generating clean energy is organic solar cells (OSCs), formed by an active layer composed of a donor material alongside an acceptor material, prepared in thin films on a nanometer scale. These devices feature advantages such as flexibility, low cost, and reduced weight, among other benefits. Conjugated polymers used in bulk heterojunction (BHJ) solar cells, based on units containing fused benzodithiophene and benzothiadiazole rings, stand out due to great results achieved in energy conversion efficiency (PCE), as presented in the literature [1, 2]. In this work, copolymers containing benzodithiophene and benzothiadiazole units were synthed, and the following synthesis parameters were evaluated: volume of solvent, mass percentage of catalyst used, and two types of catalysts. Polymerization reactions were carried out according to the Stille coupling. The obtained polymers were purified by Soxhlet extraction with methanol, acetone, hexane, chloroform, and chlorobenzene. The conjugated polymer fractions in chloroform were characterized by 1H-nuclear magnetic resonance (1H-NMR), thermogravimetric analysis (TGA), ultraviolet spectroscopy (Uv-vis), and cyclic voltammetry. The polymer yields were near 100%, although an insoluble fraction was obtained in the reaction with a low amount of solvent in the polymerization. The other reaction conditions produced only chloroform-extracted polymer, which is the one mostly used to manufacture OSC devices.

Synthesis of Niobium Phosphate Glasses and Structural Characterization by Solid State Nuclear Magnetic Resonance

Laureano Javier Ensuncho Hernandez[1], Henrik Bradtmüller[2], Hellmut Eckert[1]

[1]Universidade de São Paulo (*São Paulo*) , [2]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais*)

e-mail: laureanoensuncho@usp.br

Phosphate glasses are widely used in optical communications and solid-state lasers owing to the high solubility of photonically active metal ions in them [1]. The incorporation of transition metal ions, such as Nb_2O_5, not only improves the chemical durability of phosphate glasses, but also significantly contributes to increase both their linear and non-linear indexes of refraction [2]. However, a fundamental understanding of the structural role of niobium, which can serve either as a network modifier or as a network former, in these glasses has not been achieved. Solid-state nuclear magnetic resonance (NMR) has been proven to be a powerful tool for structural elucidation of glasses, due to its element-selectivity, inherently quantitative character, and its focus on local order [1]. From the NMR point of view, niobium features one of the most NMR-sensitive nuclei (^{93}Nb) which is 100% natural abundant. Nevertheless, it suffers from a large nuclear quadrupolar moment, and the ^{93}Nb NMR spectra are dominated by strong quadrupolar interactions, resulting in excessive line broadening and poor resolution. These challenges can be addressed by techniques involving fast MAS, wideband excitation methods and dipolar recoupling techniques [3]. Here, we report results on glasses in the system Na_2O-Nb_2O_5-P_2O_5 from two compositional series. Advanced NMR experiments have been used to characterize the local environments of sodium, phosphorus and niobium with the aim of obtaining new structural insight towards the development of new structure-function correlations.

Thermal diffusivity of silver nanofluids by thermal lens spectroscopy

Luiz Guilherme Rodrigues Sousa[1], Luis Arturo Gómez Malagón[1], Caio Vinicius Pinheiro Vital[1]

[1]Universidade de Pernambuco (*Escola Politécnica de Pernambuco*)

e-mail: lgrs@poli.br

The thermal properties of a base fluid can be enhanced by using nanoparticles. These properties can be tuned, for example, by the concentration, and shape of the nanoparticles [1]. In the case of thermal diffusivity, it can be obtained by measuring independently the thermal conductivity, heat capacity, and density, or it can be measured directly using the thermal lens technique [2]. This work aims to determine the thermal diffusivity of silver nanofluids on concentration using thermal lens spectroscopy. Silver nanofluids were fabricated using a variation of Turkevich's method, where silver nanoparticles were synthed from the reduction of silver nitrate by excessive use of sodium citrate [3]. The thermal lens experiment was performed using the double-beam setup in mismatched mode. The obtained results of the thermal diffusivity of silver nanofluids were of the order of 10-7 m^2/s which are in agreement with the results reported in the literature [2].

Thermal sensitivity and structural changes of CaF_2 nanocrystals: xEr^{3+} (x = 0.5, 1.0, 1.5, 2.0 and 2.5%), synthed by hydrothermal and coprecipitation routes for optical thermometry

Itamar Nunes de Assis Junior[1], Mohammad Reza Dousti[2], Tasso de Oliveira Sales[3]

[1]Universidade Federal Rural de Pernambuco (*Engenharia Física*) , [2]Unidade Acadêmica doCabo de Santo Agostinho - UFRPE, [3]Universidade Federal de Alagoas (*Física*)

e-mail: itamar.nunes@ufrpe.br

In order to synthe materials with excellent properties for different applications, robust synthesis routes have been improved. Here, we studied and compared the luminescent properties and thermal sensitivity of calcium nanofluorides doped with 0.5, 1.0, 1.5, 2.0 and 2.5 of the $ErCl_3$reagent (% of mass in excess). The sample were synthed following hydrothermal and co-precipitation routes. For the structural and morphological analysis, transmission electron microscopy, XDR and scanning electron microscopy were carried out. In these analyzes, the formation of the face-centered cubic crystalline structure of $CaF_2$was confirmed through the Reitveld refinement method, and the average of the crystallite is calculated to be around 55 and 68 nm for co-precipitation and hydrothermal routes, respectively. Surfaces with little roughness and porosity were found. For the luminescence measurements, the samples were excited using a laser operating at 980 nm to obtain the upconversion emissions at visible region. Moreover, we used the optical thermometry measurements to obtain the thermal sensitivity via the luminescence intensity ratio technique of thermally coupled levels. The synthesis routes were discussed in terms of the efficiency of material for the application of these nanoparticles as nanothermometers for remote temperature measurements. These results show that these nanoparticles have excellent potential for application in nanothermometers [1].

Designing and synthesizing nanomaterials with controlled properties is a critical challenge within nanoscience and nanotechnology. In particular, nanoparticles (NPs) have expanded into diverse areas ranging from light energy harvest in third-generation solar panels to biomedicine. The synthesis of NPs is usually done by chemical reduction methods that must be specifically designed for each type of material. These chemical routes unavoidably lead to unreacted precursors and additives that tend to remain in the final colloidal product, therefore, requiring vast efforts for purification. Laser ablation synthesis in liquid (LASiS) is an alternative approach for nanoparticle generation, for it allows the production of colloids directly from nearly all classes of materials in pure solvents. Considering these highly pure NPs present promising potential, in this work, we present a practical example in which hybrid Au-Ag NPs are synthesized in a fast, high-yield, two-step LASiS method, thus becoming readily available for plasmonic-based applications, such as Raman/SERS biosensors and light improved absorption in organic solar cells. Our proposed synthesis combines LASiS with 1064 nm (400 ns; 0,5 mJ) pulses from a fiber laser at 50 kHz, leading to pure Au and Ag colloids. These colloids are mixed and submitted to a second irradiation with 532 nm (5 ns; 100 mJ) pulses from a Nd:YAG laser at 10 Hz. By varying experimental conditions, we mapped the kinetics of Au-Ag alloy formation through surface plasmon resonance (UV-Vis) measurements and particle size (DLS) determination. We also investigated Au-Ag alloy NPs interaction with biological molecules containing amine, thiol, and carbonyl functional groups, a significant step for the conjugation of biomolecules such as aptamers and antibodies to create highly specific and sensitive biosensors. In addition, the broader plasmon band manifested in the alloy NPs suggests their potential for light energy harvest applications.

Understanding the RE1-xNbx–BTC (RE: Eu or Tb) MOFs obtention by femtosecond laser ablation in liquid environment

Gabriela da Costa Carvalho[1], Aldebarã Fausto Ferreira[2], Severino Alves Júnior[1], Walter Mendes de Azevedo[3]

[1]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*) , [2]Universidade Federal de Pernambuco (*Fundamental Chemistry*) , [3]Universidade Federal de Pernambuco (*Química fundamental*)

e-mail: gabriela.gcc@ufpe.br

Metal organic frameworks (MOFs) is an important class of highly porous hybrid materials. It has been synthed by many methodologies like solvothermal, hydrothermal, sol-gel and more recently, by laser ablation in water environment [1,2]. High temperatures and pressures can be reached by cavitation bubbles from laser ablation in liquid environment (PLAL) but the phenomena stages are huge different when conduced with nanosecond or femtosecond lasers [3]. Although, studies of MOFs synthesis by femtosecond laser ablation are rare orinexistent. The aim of this work is to
investigate the obtention MOFs based on europium, or terbium, and benzene-1,3,5-tricarboxyic acid (BTC), introducing niobium as a dopant to these structures, and investigate they optical and structural properties. The experiments consist to ablate the powders of Eu2O3, or Tb2O3, in DMF/water solution of BTC using a second harmonic (λ = 532 nm) of a pulsed femtosecond Nd:YAG laser. The scanning electron microscopy (SEM) presented needles structures to ER-BTC and X-ray diffractometry showed reminiscent peaks of oxides on powder obtained. Furthermore, the samples were analyzed by FTIR, Raman, TGA and Luminescence measurements.

Acknowledgments

X-Research on 2D Materials

Bottom-up fabrication of graphene nanoribbons: from ultra-high-vacuum to device integration

Gabriela Borin Barin[1]

[1]Swiss Federal Laboratories for Materials Science and Technology (*nanotech@surfaces laboratory*)

e-mail: *gabriela.borin-barin@empa.ch*

Graphene nanoribbons (GNRs) show exciting properties deriving from electron confinement and related band gap tunability[1]. The ability to tune GNRs' electronic and magnetic properties at the single atom level makes them an ideal platform for a wide range of device applications, from classical transistors to spintronics. In this talk, I will give an overview of the necessary steps to bring GNRs from ultra-high vacuum (UHV) to device integration focusing on the synthesis, characterization, and transport measurements of atomically-precise graphene nanoribbons. After the UHV bottom-up growth, GNRs are transferred using different transfer methods based on wet processes, such as polymer-free[2]and an electrochemical delamination method[3], as well as semi-dry/dry-transfer methods. Those processes allow the characterization of GNRs fingerprint modes via Raman spectroscopy[3,4]and the characterization of their electronic properties on decoupled substrates such as quasi-free-standing graphene. Next, I will show our progress on integrating different armchair GNRs (5-, 9-, 17-AGNRs)[5,6]into field-effect transistors with different gate and contact configurations. As a brief overview, we recently demonstrated the highest Ion current GNR-FET device to date by using a double-gate configuration[7]. 9-AGNR-FETs showed I_{on}currents up to 12μA and I_{on}/I_{off}up to 10^5. By integrating 9-AGNRs into FET devices using graphene[8]and carbon nanotubes[9]as electrodes, we also demonstrated tunable multi-gate devices showing quantum dot behavior with rich Coulomb diamond patterns.

Contributions of the Laboratory of Advanced Materials Chemistry – LAQMA-UFPR in layered materials, emphasizing layered double hydroxides and hydroxide salts

Fernando Wypych[1]

[1]Universidade Federal do Paraná (*Química*)

e-mail: wypych@ufpr.br

Layered or two-dimensional (2D) materials belong to an important class of compounds with several industrial applications, to which 2 Nobel Prizes were attributed: 2010 - Physics - A. Geim, K. Novoselov - Graphene and 2019 - Chemistry - J.B. Goodenough, M.S. Whittingham, A. Yoshioro - Lithium batteries. After some contributions of Brazilian researchers, in 1992 was founded in the Federal University of Paraná, the LQES - Laboratory of Solid State Chemistry, nowadays LAQMA - Laboratory of Advanced Materials Chemistry. As far as the author know, the first works in Brazil involving exfoliation of MoS2 and use of the single layers in polymer nanocomposites were developed in this laboratory by the Scientific Initiation students [1,2]. These works started after the publication of the first synthesis of the metallic 1T-MoS2 in 1992 by the same author [3]. Probably the first atomic resolution image of 2H-WS2 using STM was published in a Brazilian Journal in 1998 [4], after the development of the STM technique just in 1986. Due to the experimental difficulties, lack of students and financial support, LAQMA was redirected to the synthesis, characterization, and application of Layered Double hydroxides - LDH and probably for the first time inBrazil, Layered Hydroxide Salts - LHS [4]. The objective of the present talk is to describethis evolution and the contributions of LAQMA in the scenario of layered materials in Brazil, emphasizing LDH and LHS, despite the scarce financial support since 1992, when the activities in the laboratory began. Future perspectives will also be addressed. Acknowledgements: This study was financed by CAPES - Finance Code 001, CNPq (FW: 300988/2019-2) and FINEP. FLEXIBLE ELECTRONICS BASED ON CONJUGATED POLYMERS AND 2D MATERIALS

Lucimara Stolz Roman[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: romanlucimara@gmail.com

The combination of conjugated polymers, oxides and carbon nanostructures can be an interesting way of organizing the nanostruture of thin films and develop new optoelectrical properties. The development of electronic devices based on thin films as electrodes or active layers offer some processing advantages and new possibilities in the manufacture of these devices, such as flexibility and large areas. The interest in this research area has grown significantly, presenting many innovations, whether in the synthesis of new materials, in the understanding of optoelectronic properties or in new device geometries allowing the increase of their efficiencies. The solution processed devices can take the advantage of nanostructured inks to allow their fabrication using spin coating or slot die coating in flexible substrates. In this work, some examples of the combination of these materials in thin films will be presented in the fabrication of electronic devices obtained by simple mixture in a common solvent; generated by interfacial synthesi and by miniemulsion technique. In addition, examples of electronic devices such as gas sensors, active layers of solar cells, COVID optical sensors and electrodes obtained with this approach will be presented and discussed.

From Electrochemical Sensors to Microfibers: Advancements in Graphene-Based Technologies

Cecilia de Carvalho Castro e Silva[1,2]

[1]Mackenzie Presbyterian University (*School of Engineering*) , [2]Mackenzie Presbyterian Institute (*MackGraphe - Mackenzie Institute for Research in Graphene and Nanotechnologies*)

e-mail: cecilia.silva@mackenzie.br

Graphene-based sensors have received significant interest due to their unique properties. These properties include high electrical conductivity and high surface area. The 2D structure of graphene allows all carbon atoms to be exposed to the surroundings, making it an ideal platform for adsorbing and detecting molecules, which leads to increased sensitivity. Graphene is also biocompatible, providing a favorable environment for the immobilization of bioreceptors, such as antibodies, enzymes, DNA, and aptamers [1]. Thus, these properties make graphene an appealing transducer material in biosensors. In this presentation, an overview will be provided of the fundamentals and applications of graphene and its derivatives, such as graphene oxide (GO), reduced graphene oxide (rGO), and laser-induced graphene (LIG), in the development of electrochemical sensors and microfibers [2]. The presentation will explore the development of high-sensitivity devices based on graphene field effect transistors (FETs) and low-cost LIG-based electrochemical sensors [3]. Furthermore, a straightforward method based on 3D flow-focusing microfluid devices will be demonstrated to produce GO microfibers, with good control of thickness and length. Additionally, the presentation will explore both thermal and microwave treatments that can obtain rGO microfibers with spectroscopic and electrical properties like CVD graphene. These promising candidates are suitable for the development of flexible FETs and microelectrodes.

Layered Materials for Optoelectronics and Quantum Technologies

Andrea C. Ferrari[1]

[1]University of Cambridge

e-mail: acf26@cam.ac.uk

Graphene and layered materials (LMs) have great potential in photonics and optoelectronics, where the combination of their optical and electronic properties can be fully exploited, and the absence of a bandgap in graphene can be beneficial. The linear dispersion of the Dirac electrons in graphene enables ultra-wide-band tunability as well as gate controllable third-harmonic enhancement over an ultra-broad bandwidth, paving the way for electrically tunable broadband frequency converters for optical communications and signal processing. Saturable absorption is observed as a consequence of Pauli blocking and can be exploited for mode-locking of a variety of ultrafast and broadband lasers. Graphene integrated photonics is a platform for wafer scale manufacturing of modulators, detectors and switches for next generation datacom and telecom. Heterostructures based on LMs have properties different from those of their individual constituents and of their three dimensional counterparts. These can be exploited in novel light emitting devices, such as single photon emitters, and tunable light emitting diodes. LMs have potential for quantum technologies, as scalable sources of single photon emitters (SPEs). Quantum emitters in LMs hold potential in terms of scalability, miniaturization, integration. Generation of quantum emission from the recombination of indirect excitons in heterostructures made ofdifferent LMs is a path with enormous potential. I will overview production, characterization and application of graphene and LMs, focusing on optical and quantum applications.

Magneto-optical properties of van der Waals heterostructures

Yara Galvão Gobato[1]

[1]Univerdade Federal de São Carlos (*Departamento de Física*)

e-mail: yara@df.ufscar.br

Transition metal dichalcogenides (TMDs) are attractive van der Waals materials for fundamental physics, and for the next generation of optoeletronics and spintronics devices. Magneto-optical spectroscopy is a useful technique to investigating spin-valley coupling and exciton physics in two dimensional (2D) materials. In particular, under perpendicular magnetic field, interesting phenomena can be observed such as valley Zeeman splitting and magnetic-field-induced valley polarization. Twisted van der Waals (vdW) heterostructures based on TMD materials exhibit periodic variations, leading to a new type of in-plane superlattice known as moiré superlattice/pattern which modifies considerably the opticaland magneto-optical properties of excitons in vdW heterostructures. Furthermore, 2D ferromagnetic/antiferromagnetic vdW materials are promising systems for a new generation of spintronics or opto-spintronics devices. Particularly, by combining 2D magnets with TMDs, there is the advantage to use magnetic proximity exchange effects for making TMDmaterials magnetic. Furthermore, the physical properties of these materials or based vdW heterostructures are very sensitive to the number of layers, applied gate voltage, strain, twisted angles between the layers, spin-dependent charge transfer, magnetic proximity effects and etc, giving unprecedented controllability for their optical/magnetic properties. In this talk, I will present our recent investigation on the impact of smooth/local strain, doping and moiré pattern on magneto-optical properties of TMD heterobilayers and 2D magnet/TMD vdW heterostructures.

NANOSTRATEGIES FOR MOLECULE ADSORPTION WITH BIOLOGICAL AND ENVIRONMENTAL INTEREST

Solange Binotto Fagan[1]

[1]Universidade Franciscana (*Nanociências*)

e-mail: solange.fagan@gmail.com

In this talk it will be presented results combining ab initio simulations and molecular docking to develop complex models associated with experimental results. Mainly, carbon nanomaterials of different dimensions will be explored, applied in systems of biological interest [1], such as drugs, proteins, etc. and of interest for environmental remediation, such as adsorption of pollutants in liquid media [2].

It is noteworthy that this composition of methods, via nanoarchitectures, allows exploring different properties of nanosystems, reducing the experimental cost and creating new technological applications.

In some studies, we used experimental data from collaborating groups to corroborate the theoretically obtained analyzes and allow for innovative results for the advancement of nanoscience and nanotechnology.

Screening nanocatalysts for agrochemical neutralization: selective functionalization and effects of coverage, support, group and neighboring

André H. G. Martinez[1], Vinícius O. Costa[1], Mayara Gabriela Gonçalves[1], Gabriel C. B. Gomes[1], Yane Honorato Santos[1], Sergio H. Domingues[2], Aldo José Gorgatti Zarbin[3], Elisa Souza Orth[4]

[1]Universidade Federal do Paraná, [2]MackGraphe, Mackenzie Presbyterian University, [3]Universidade Federal do Paraná (*Departamento de Química*) , [4]Universidade Federal do Paraná (*Chemistry*)

e-mail: andregonez13@gmail.com

Agrochemicals and chemical warfare have a lot in common, since many belong to the class of organophosphates. Our group has been focused in combating organophosphates, seeking nanocatalysts for degradation and detection. We pursued site-selective mono and bifunctionalization of various nanomaterials, such as graphene oxide and carbon nanotubes, with thiol, imidazole, hydroxamate groups (covalently linked) and metallic nanoparticles (Ag, Ni). The catalysts were obtained as powder and thin film. For the bifunctionalization, two different groups were anchored on specific sites of the material: both carboxylic acid and epoxy sites for the graphene oxide. The catalysts are able to act as neutralizing agents for organophosphates, accelerating the process to less than 1 day, that otherwise could take millions of years. The bifunctionalized catalysts showed an interesting relationship between coverage degree, group identity and neighboring effects. The materials with the highest degree of functionalization were not the best catalysts, attributed to cooperative effects between neighbouring groups that promote multiple catalyses. In addition, a higher coverage by functional groups can disturb or even inhibit possible catalytic mechanisms, either by steric effect or non-ideal positioning of the groups. This finding was extremely important since it shows that the functionalization process pursued should be driven by the application wanted since not always what we expect as a better functionalization methodology will lead to the best response for a specific application. The catalysts also showed a dual function: could be used as sensors (surface enhanced Raman spectroscopy, electrochemical) for these toxic agents. In summary, indeed the strategic design of various nanomaterials seeking optimal catalysts opens a myriad of possibilities for achieving prominent catalysis, especially for promoting worldwide chemical security by combating agrochemicals and chemical warfare.

Synergetic enhancement of quantum yields ofmonolayer WS_2 by proximal metal gating

Jeongyong Kim[1]

[1]Sungkyunkwan University (*Energy Science*)

e-mail: j.kim@skku.edu

Quantum yield (QY) is a crucial performance factor of the semiconductor to be considered as light-emitting photonic devices. While the structural defects are the main source of degrading the quantum yield of bulk semiconductors, two-dimensional semiconductors display the major channel of non-radiative decay of excitons due to strong interaction among the excitons even in moderate exciton density conditions, In this presentation, I willdiscuss some of the strategies that we developed to suppress or bypass the exciton interaction, which lead to enhancing the QY of monolayer WS_2, specifically the use of proximal metal plates or hBN substrate and applying out-of-plane electric field. [1-3]

e-mail: pedrovenezuela@id.uff.br

Two-dimensional (2D) semiconducting materials as active layers in photovoltaic devices is a subject that has attracted a lot of attention in the last years. Nowadays, the most employed materials for this kind of application are transition metal dichalcogenides (TMDCs), which are semiconductors with chemical configuration MX_2, where M is a transition metal such as Mo, W, and X is a chalcogen atom such as S, Se, or Te. However, many other 2D materials have also been proposed. As far as TMDCs are concerned, while significant attention has been given to single layer TMDCs, a limited number of works have addressed the few layer case which is particularly relevant for photovoltaic devices.

Herein, we studied the electronic and optical properties of few layer TMDCs composed of Mo, W, S, and Se within the GW and Bethe-Salpeter approach. First-principles calculations based on density functional theory were carried out using the Quantum ESPRESSO package. The many-body perturbation theory and Bethe-Salpeter calculations were performed using YAMBO code. We address the photovoltaic performance of these TMDCs estimating the spectroscopic limited maximal efficiency (SLME) as a function of the thickness of the semiconductor. We compared the different TMDCs to known materials used in photovoltaics paving the way for efficient nanoscopically thin solar cells.

We have also employed the same methodology described above to study a polymorph of h-BN that has been theoretically proposed recently. This material, named as orthorhombic diboron dinitride (o-B2N2), is a direct band gap semiconductor. We show that the band gap energy of o-B2N2 varies strongly with number of layers and consequently it has potential to be employed in photovoltaic devices.

3d transition metal coordination on monolayer MoS_2: a facile doping method to functionalize surfaces

e-mail: walnercosta@gmail.com

Earth abundant metals-based catalysts can be found as a good option for new catalysts with remarkable activity in comparison with Pt-based, as TMDs like MoS_2, $MoSe_2$ and WS_2 have shown to possess activity towards HER, mostly on the edge, and the basal plane with characteristic low activity. Manipulating the surface of these materials can be a good way to enhance the overall activity and activate the basal plane. Due to the nature of the dichalcogenide atoms, having free electron pairs acting as a Lewis base, one can coordinate metal atoms, like 3d transition metals ions, as a Lewis acid, creating new and stable functionalized materials [1]. In this work we show a facile way of functionalizing TMDs surfaces with 3d TM atoms. X-ray Photoelectron Spectroscopy (XPS) results indicate that depending on the doping atom, one can have a p or n-type doping, as Ni and Co species can donate electron density, although Cr and Cu can take electron density. Photoluminescence Spectroscopy shows by the Exciton/Trion ratio that a minimum amount of doping atom is sufficient for changing this ratio, indicating electron density changes. High Resolution-Transmission Electron Microscopy (HRTEM) demonstrates for Ni-doping that the atoms are atomically dispersed on the surface [2]. Therefore, the formation of TMD-TM complexes can lead to a controllable way of modulating the material’s properties.

e-mail: leticia.ildefonso@estudante.ufjf.br

In recent years, transition metal dichalcogenides (TMDs) have been widely studied due to their unusual optoelectronic properties. Recently, the study of defects in these materials allows the application in semiconductor devices, since defect sites locally disturb the crystalline lattice, leading to peculiar effects. For example, punctual defects (zero-dimensional) are the single-photon emission source, which is an important role in the quantum information devices industry [1], and highly ordered defect lines (one-dimensional) exhibit charge wave densities along themselves [2]. In this context, Raman and photoluminescence spectroscopies have been a powerful tool to quantify and identify punctual and linear defects in 2D materials. In this work, we synthesized monolayers of WS2 via chemical vapor deposition (CVD), bombarded these samples with He ions and we verified the existence of two Raman bands and two new electronic transitions, present in the photoluminescence spectra, activated by punctual defects. Linear defects were produced by lithography, also with He ions, and show promising results, such as the anisotropy of some Raman modes. First-principle calculations were performed to obtain the electronic and phononic dispersion, thus inferring the origin of the observed effects in Raman and PL spectra. The same punctual defect model that allows to predict the crystallinity of graphene and molybdenum TMD [3] was employed to visualize when WS2 begins to become amorphous. So, this work makes possible the identification of defects in tungsten TMDs, which are much used in the technology industry of semiconductors.

Defect engineering on the basal plane of ultra-largeMoS2 monolayers for electrochemical hydrogen production

Leonardo Hideki Hasimoto[1,2], Cláudia de Lourenço[3], Ana Beatriz Sorana de Araújo[3], Murilo Santhiago[3,4]

[1]Universidade Federal do ABC (*Nanociências e Materiais Avançados*) , [2]Brazilian Center for Research in Energy and Materials (*Laboratório Nacional de Nanotecnologia*) , [3]Brazilian Center for Research in Energy and Materials, [4]Brazilian Nanotechnology National Laboratory

e-mail: leonardo.hasimoto@lnnano.cnpem.br

The basal plane of molybdenum disulfide (MoS2) monolayers displays the largest area available for electrocatalysis, however, due to the lack of active sites on this region the electrocatalytic activity toward electrochemical hydrogen production is poor [1]. Thus, many defect engineering routes have been used to tune the electrocatalytic activity of the basal plane to improve its performance. However, it is still very challenging to control the position, size, and propagation of defects on the basal plane of MoS2 monolayers by most of defect-engineering routes. Thus, in this work, we will show the fabrication of arrays of defective regions on supported and free-standing ultra-large MoS2 monolayers. First, ultra-large MoS2 monolayers were prepared directly on conductive substrates using a simple and fast electrochemical thinning method [2]. Next, gallium-FIB was used to etch MoS2 and open reactive windows on the basal plane. The dose applied to etch a controlled depth on MoS2 was calibrated using atomic force microscopy. The arrays were characterized using Raman spectroscopy and photoluminescence (PL) experiments, thus confirming the introduction of defects on the basal plane. The impact of each dose on the electrocatalytic activity toward hydrogen evolution reaction was measured by fabricating microelectrodes. TEM analysis also revealed the formation of amorphous regions. In addition, we will show the fabrication of arrays of etched edges using O2 plasma and electron-beam lithography.

Doped 2D diamond: properties and potentialapplication

Bruno Ipaves[1], João Francisco Justo[2], Lucy Vitória Credidio Assali[1]

[1]Instituto de Física da Universidade de São Paulo, [2]Escola Politécnica de Universidade deSão Paulo

e-mail: ipavesbruno@usp.br

Graphene is the most popular two-dimensional (2D) material, being a zero-gap semimetal with a honeycomb carbon structure and sp^2 hybridization. It is the fundamental building block for several other nanomaterials, such as fullerenes, nanotubes, graphite, and the single-layer diamond (2D diamond). Furthermore, the properties of carbon-based materials could vary considerably by doping and/or functionalizing them with several distinct types ofatoms and by combining them with different 2D systems [1]. Due to recent developments inthe synthesis and characterization of 2D materials, the 2D diamond has received great attention, with promising applications in several fields, such as batteries, quantum computing, nano-optics, and nanoelectronics. In this context, we explored the structural, thermodynamic, dynamic, elastic and electronic properties of C_4X_2 (X = B or N) systems. These structures are made of three graphene sheets in which four C atoms are bonded covalently (2D diamond-like) in each unit cell. The two external layers are 50% doped with X substitutional atoms and, hence, each X atom is bonded to three C atoms. We found that the C_4X_2 systems present stiffness comparable to that of the diamond. Additionally, the C_4N_2 nanosheets have wider indirect bandgaps, while the C_4B_2 systems have narrower direct bandgaps when compared with the pristine 2D diamond. These results provide chemical routes to tune the electronic properties of 2D diamonds by doping them for specific applications, such as nano-optoelectronic.

The twist angle between the monolayers directly controls the effects of periodic moiré potential in transition metal dichalcogenides (TMDs) bilayers [1]. Nonetheless, such effects may appear even more pronounced at twisted homobilayers, since the absence of lattice mismatch promotes the appearance of larger Moiré superlattices(ref) and reconstructed domains. Novel features arising from intra- and interlayer excitons, such as their ultrafast formation and charger transfer, long population recombination lifetimes, and binding energy of ~150 meVs[2,3], turn TMD hetero-structures into an attractive device for the study and manipulation of optical and transport prop-erties via electrical fields and electrostatic gating[4].

In this work, we explore the ability to control excitonic complexes in MoSe2/MoSe2 twisted bi-layers (t-BL) by performing gate-dependent microphotoluminescence (μPL) spectroscopy at room temperature. We observe the energy tunability of several meVs occurring at the emission of excitonic complexes derived from the t-BL region compared with MoSe2 monolayer response. More-over, we investigate the twisted-angle dependence of valley properties by studying two hetero-structures that present distinct stacking angles, 0 degrees (R-stacking) and 18 degrees. Our results suggest that the two prominent interlayer exciton species in the R-stacking t-BL, which can be individually manipulated, may be associated with the moiré superlattice formation. Although our findings still require further understanding, we present an electrical control of excitonic complex-es at room temperature, poorly explored in the literature of TMD hetero-and homobilayers, and open up new pathways to survey applications in semiconducting optoelectronic field.

e-mail: bsarchanjo@inmetro.gov.br

Graphene, a two-dimensional sp2 carbon structure, is a system that comprises exciting possibilities to demonstrate new physics and promising applications, many of which can be appreciated only by means of nanoscale modifications in its structure. In this talk, we will journey through the use of nanotechnology tools to understand the behavior of this material and also, tune its properties for desired applications. It will be discussed the metrology of defects and disorder in graphene and the use of focused ion beam milling, i.e. Ga (Focused Ion Beam - FIB) or He (Helium Ion Microscope - HIM) [1], in the fabrication of periodical patterns and devices. Also, we are going to show our work on revealing lattice disorder, oxygen incorporation and pore formation in laser induced two-photon oxidized graphene [2]. Our work is developed using FIB, HIM, high resolution transmission electron microscopy (HRTEM), electron energy loss spectroscopy (EELS), atomic force microscopy (AFM) and Raman spectroscopy. Finally, we are going to show our efforts in optical characterization at resolutions bellow the limit of light diffraction through the use of tip enhanced Raman spectroscopy (TERS) [3-5].

This presentation will focus on Raman, NanoRaman and Correlative Spectroscopy applied to Materials Science and Engineering of Nanomaterials. The principles of applied Raman spectroscopy and Raman imaging (the importance of spectral resolution for imaging) will be approached from theory, application and instrumentation as the main topics for two-dimensional (2D) materials characterization for a wide range of applications such as biomaterials and life sciences. Raman and nanoRaman Spectroscopy are one of the only techniques capable of providing precise and non-destructive analysis combined with high resolution images. Raman spectroscopy provides valuable information such as chemical and structural composition. Based on the light-matter interaction, the Raman technique can perform characterizations through mapping measurements, obtaining relevant information, such as: particle size distribution, homogeneity, grain size, phase changes and various other characteristics of the sample through the chemical evaluation of the material. The effects of chemical bonding, strain, and crystal size will be covered, and we will show how to measure and image these features. In addition, we will discuss combined laser-excited photoluminescence and Raman scattering images of two-dimensional (2D) crystals to reveal the spatially variable solid-state structure of these nanomaterials. The development of the instrumentation allows the syllabic separation of Raman spatially co-localized and correlated with other techniques, such as Photoluminescence, Fluorescence, Scanning Electronic Microscopy and Atomic Force Microscopy, being able to reach resolutions on the nanometric scale. The techniques can be applied in several areas of knowledge, such as pharmaceuticals, photovoltaics, graphene, cells, nanoparticles, nanoplastics, among others.

Phyllosilicates minerals are an emerging class of naturally occurring layered insulators with large bandgap energy that have gained considerable attention from the scientific community. This class of materials has been explored recently at the ultrathin two-dimensional level due to their specific mechanical and optoelectronic properties, which are crucial for engineering novel devices. Phyllosilicates have lamellar structures and can be embedded into van der Waals heterostructures due to the possibility of exfoliation down to monolayers and easy handling. Due to these properties, phyllosilicate minerals can be considered promising low-cost nanomaterials for electronics, photonics, and optoelectronics future 2D-based device applications. Here, we present features of these nanomaterials that are relevant to their use in potential 2D-based applications [1-3], discussing the major challenges in working with them.

Organic ammonium-based cations are used to prepare low-dimensional perovskite structures, allowing fine-tuning of perovskite's optical and electronic properties. Recently, chiral organic cations have been introduced to produce low-dimensional perovskites. The asymmetric hydrogen (H-) bonding between the H in the ammonium group and the halogen in the perovskite structure, breaks the centrosymmetry of the crystal, resulting in chiroptical activity in 2D perovskites. Despite the growing interest in chiral perovskites, the fundamental process underlying their crystallization and film formation remains unknown. For example, 1D phase impurities in 2D chiral perovskite systems are often reported, but strategies to circumvent this issue are still lacking. In this study, we investigate the formation of 1D phases in 2D perovskites based on chiral methylbenzylammonium cations and their racemic mixture. By combining in- and ex-situ characterizations, we demonstrated that the solvent choice, annealing condition, and spatial configuration of the organic cation play a significant role in determining the final film's microstructure, phase purity, and crystalline orientation. We propose that the 2D and 1D phases are the kinetic and thermodynamic products of the film formation reaction, respectively. The film formation dynamics are shown to be influenced by the solvent's coordination ability, allowing strategies to control phase purity in chiral 2D perovskites. We also find that the chirality of the organic cation and film processing condition impacts the degree of energetic disorder, residual lattice strain, and in-plane conductivity of the films. This work provides relevant insights for the development and future integration of chiral perovskites into optoelectronic and spintronic devices.

e-mail: jose.padilha@ufpr.br

2D van der Waals heterostructures have emerged as an important class of materials due to their unique properties, which are derived from the combination of different 2D materials with complementary properties. These heterostructures allow for the creation of complex electronic and optoelectronic devices with unprecedented functionality and performance. This work presents a comprehensive first principles study of ZnX and CdX (X = S, Se, Te) direct band gap semiconductors and their van der Waals heterostructures. The electronic and optical properties of these semiconductors were analyzed calculations revealed that ZnX and CdX (X = S, Se, Te) are all direct band gap semiconductors. Furthermore, the electronic band structures and density of states were calculated for the studied semiconductors, and the results showed that ZnX and CdX semiconductors have similar electronic structures, with the conduction band minimum (CBM) and valence band maximum (VBM) located at the Γ point in the Brillouin zone. However, the width of the band gap and the effective mass of the charge carriers vary with the type of semiconductor.The study also investigated the electronic and optical properties of van der Waals heterostructures composed of ZnX and CdX semiconductors. The heterostructures were formed by stacking the different layers of the semiconductors with different orientations. The results show that the band alignment at the interface between the two semiconductors depends on the type of semiconductor and the stacking configuration. The heterostructures exhibit interesting optical properties, such as type-II band alignment, which is attractive for optoelectronic applications.The results obtained can be useful in the design and development of novel semiconductor devices and materials for optoelectronic and photovoltaic applications.

Grafeno Brasil Platform: a booster for consolidation of graphene-based products' market in Brazil

Mateus José Fernandes Martins[1], Jailton C Damasceno[2], Oleksii Kuznetsov[3], Joyce Rodrigues Araujo[4]

[1]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*DIMCI*) , [2]Instituto Nacional de Metrologia, Qualidade e Tecnologia, [3]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*DIMAT*) , [4]Divisão de Metrologia de Materiais

e-mail: mateus.jfm@gmail.com

The "Grafeno Brasil" network is particularly well suited for companies and institutions working in the field of graphene research and development. The network''s main goal is topromote innovations in Brazilian industry through the development and placing on the market new graphene-based products that meet the needs of customers, on the one hand,and all regulatory requirements, on the other hand. "Grafeno Brasil" platform puts on itsbasis the principles of demand-side innovation policy with the introduction of feedback linkages between supply and demand in the innovation process. One of the key features of "Grafeno Brasil" network is its ability to match the demands (including unmet or latentdemands) of companies for innovation with the available capacities and resources of research institutions and, in general, of public sector. This approach to innovation by supporting the demand side, including utilization of demand-side instruments such as regulation and standardization, is supposed to create more efficient and effective collaborations between all actors, reducing time-to-market for new products and technologies. Through its on-line platform, the Grafeno Brasil network will provide a variety of tools and resources to facilitate communication and collaboration between its members, as well as to help forward the coordination between the regulators and the different stakeholders. In conclusion, the Grafeno Brasil network is the innovative and dynamic platform, which is designed to help diffusing innovation and fostering collaboration between companies and research institutions. Its unique approach to matching the demands and capacities creates new opportunities for growth and development in various industrial sectors and business areas, as well as promotes the advancement of cutting-edge technologies such as graphene-based technologies.

e-mail: flavioferrs@gmail.com

The well-established two-dimensional (2D) material graphene is anticipated to feature extraordinary near-field optical properties in the terahertz (THz) frequency range [1]. However, the experimental interrogation of such phenomena is non-trivial due to the intrinsic dimensionality mismatch between atomically thin graphene and the wavelength of the THz radiation reaching hundreds of micrometers. This task becomes even more challenging in the THz gap (0.1 - 10 THz) wherein powerful light sources are scarce [2]. Nevertheless, modern nanoscopy techniques coupled to unique, highly brilliant THz light sources have been demonstrated to accomplish an experimental investigation of such 2D materials [3]. In this work, we apply a scattering-scanning near-field optical microscope (s-SNOM) illuminated by THz radiation of a tunable free-electron laser (FEL) to investigate the near-field optical response of graphene within the THz gap (1.5 – 6.0 THz). We firstly demonstrate that graphene takes on an optically metallic character at around 2 THz. In this frequency range, the driving THz field enables quasi-static response associated to the relaxation of the Gr charge carriers. Secondly, we find the graphene to feature a distinct field-enhancement effect (FEE) at 3.8 THz, meaning a significantly increased optical contrast and sharpness of the near-field optical images. Through theoretical analysis based on the polariton dispersion relation and near-field modeling, the FEE can be attributed to a plasmonic resonance of graphene near 3.0 - 6.0 THz. We believe these novel aspects of graphene nanooptics in the THz range to prove valuable for future graphene-device-based studies and technological applications.

How near-field infrared microscopy enables vibrational analysis of natural 2D nanocavities for water confinement

Raphaela de Oliveira[1,2], Alisson Ronieri Cadore[3], Raul O. Freitas[2], Angelo Malachias de Souza[1], Klaus Krambrock[1], Ingrid David Barcelos[2]

e-mail: raphaeladeog@ufmg.br

Water is the matrix of life and its confinement in nanocavities is a central topic from geophysics to nanotribology. Phyllosilicate layered minerals are natural nanocavities for water due to their capacity to hydrate by confining water molecules in interlamellar space. However, the hydration of phyllosilicates at the nanoscale is not a fully understood process and depends on the geological specimens. In order to obtain information about the confinement of water in phyllosilicate minerals, we can investigate the vibrational properties of these systems, since water molecule has three vibrational modes active in infrared (IR). However, accessing the vibrational assignment of an isolated few-layer (FL) phyllosilicate flake through far-field analysis in IR absorption experiments is extremely challenging. Limited by diffraction, these experiments are unable to reach nanometric resolution since the wavelengths of IR radiation are micrometric. Evidently, searching for the vibrational response of few water molecules confined in this two-dimensional (2D) system is even more challenging. In this perspective, scattering-type near-field optical microscopy (s-SNOM) and synchrotron infrared near-field spectroscopy (SINS) are key toolsto reach sub-diffractional nanometric resolution in the study of 2D systems.

In this presentation, we will provide technical aspects that make s-SNOM and SINS powerful techniques in nano-optics and local chemistry studies of a variety of natural 2D phyllosilicates [1]. We will demonstrate SINS as a robust alternative to perform opto-vibrational characterization of FL-phyllosilicates by enabling local nanospectroscopy. As unique result, we will unravel the water confined in an ultrathin phyllosilicate flake by IR s-SNOM nanoimaging. This result provides a way to access the outstanding capacity of phyllosilicate minerals to absorb water and act as natural nanocavities that can be explored in future technologies.

e-mail: wellersonramoss@gmail.com

In this work, we have synthed 2D MoS2/MoSe2 heterostructures by chemical vapor deposition (CVD) in a one-pot, two-step configuration: the second crystal was directly grown on top of the first, without mechanical transfer. Indeed, most vertically stacked HSs go through nanomechanical manipulations resulting in nonhomogeneous residual strain, polymer residues or mechanical fracture. Also, among others, an advantage of such heterostructures is that they can be considered as pristine vertical HS, since they have a clean interface between layers. Moreover, another interest in studying such material is that the bottom and top layers are almost the same. They only differ by the chemical nature of the chalcogen atom, and consequently the of the metal-chalcogen bond is slightly different. The photoluminescence and vibrational analyses indicate shifts in the band positions when compared to monolayer MoS2 or MoSe2. We propose that this behavior is mainly driven bya mechanical strain that originates from the synthesis, since the HSs tend to counterbalancethe lattice mismatch between the top and the bottom crystals. Our findings are corroboratedby DFT calculations, where electron and phonon dispersions of strained materials reproduce qualitatively well the experimental data. Also this work permits us to compare the interaction between constituent layers of HS assembled by transfer or by direct growth and their role to tune the physical properties of those nanomaterials for specific applications in nanoelectronics.

e-mail: francisco.maia@lnls.br

The electromagnetic field can exhibit distinct structures in the far and near-field radiation zones [1]. Aspects of such peculiar behaviors have been seen from the study of high momenta polaritons observable only in the near-field zone of polar two-dimensional (2D) crystals [1] like hexagonal boron nitride (hBN) and alfa molybdenum trioxide (αMoO_3). It is well documented that such polaritons exist in the range between the transverse (ω_{TO}) and longitudinal (ω_{LO}) optical phonons, wherein the real part of the media's electrical permittivity (ε) is negative. However, close to such spectral limits, the polaritonic activity vanishes, whilst other interesting near-field phenomena rise as fascinating optical effects found close to ω_{LO} when $\varepsilon \to 0$, which creates the epsilon near zero (ENZ) spectral region. Decoupling of magnetic and electric fields in Maxwell equations, infinite impedance, slow-light and super transmission/reflection [2, 3] are exquisite effects originated from the ENZ condition. In this presentation, we will show that 2D hBN and αMoO_3 emit light in the near-field zone, in ENZ bands where $1 \leq Re[\varepsilon] \leq 0$, due to ENZ resonances of the local density of states. Such discoveries are experimentally recorded by real-space nanoimaging in the mid and far-IR using a scattering-scanning near-field optical microscope coupled to quantum cascade lasers and a free electron laser. Proper discussion on the physical implications is given from theoretical predictions. Supported on quantitative convergence of experiment and theory, we demonstrate that ENZ resonances are general effects of 2D polar hyperbolicmedia that can be further controlled by temperature, strain, and electrical gating.

Acknowlegments:

Luminescence enhancement of CVD grown Ga-dopedWS_2 monolayers

Shuai Zhang[1], Andre N. Barbosa[1], Fernando Lázaro Freire Junior[1] [1]Pontifícia

Universidade Católica do Rio de Janeiro (*Física*)

e-mail: zhangshuai0018@outlook.com

Monolayer Tungsten disulfide (WS_2) is a direct band gap semiconductor that boasts excellent luminescence properties, which may be useful in many optoelectronics applications. Through the incorporation and control of impurities or defects in the lattice of WS_2, one can significantly alter a specific property to improve the performance of devices for a target application, such as photonics and catalysis. In this study, we utilized in situ doping strategy to synthe Ga-doped WS_2. Our results indicate that Ga- doped WS_2luminescence is enhanced by nearly four times when compared to pristine WS_2. To confirm the incorporation of Ga in WS_2structures, Resonance Raman spectroscopy and X-ray photoelectron spectroscopy (XPS) were utilized as characterization methods. Raman spectroscopy revealed that the presence of Ga affects the crystals' vibrational properties, where disorder-related effects due to a higher density of defects are directly affected, where the LA(M)/[A_{1g}(M)-LA(M)] peak intensity ratio increased due to the presence of Ga impurities in the lattice. In particular, the small redshift observed in the A1g mode indicates that Ga species are n-doping the monolayers, which is compatible with the literature results seen elsewhere. Also, from the XPS spectrum, it is clear to observe an energy blueshift in W4f and S2p regions in Ga-doped WS_2compared with pristine WS_2. Especially, there is an evolution of blueshift in Ga2p region with increasing Ga dopant. These results prove the presence of Ga in the WS_2lattice.

Magneto Dependence of Excitonic States of TwistedWSe2

e-mail: mclarago@gmail.com

Monolayer transition metal dichalcogenides (TMDs) exhibit rich physics related to their excitonic complexes. In these materials, the reduction of the dielectric screening collaborates with the intensification of Coulomb interaction and, consequently, the formation of exciton with high binding energy and other complexes involving more carriers. In particular, TMDs present spin-orbit coupling, promoting valence and conduction band splitting, and valley structure can be verified with circularly polarized light. In a slightly different system, the band structure and the excitonic properties can be tuned if two layers of TMDs are placed, one on top of the other with a twist angle, producing a twisted WSe2 material (t-WSe2). In our work, we investigate the excitonic states of high-quality t-WSe2 encapsulated in hBN crystals. We investigate the photoluminescence''s polarization and magneto dependency at low temperatures. Comparing with the monolayer case, we observe unexpected high valley polarization for the exciton and negative biexciton. Moreover the similar effect was measured for other unidentified excitonic complexes with energies closed to reported values for dark trions and local excitons, which generally shows small valley polarization. Finally, we observe a new emission that rises for high magnetic fields (B >7 T) is verified whose identification is still under progress. Our results may reveal the quantum confinement effects of Moiré excitons in twisted semiconducting 2D heterostructures.

Multilayer Graphene as an Endoreversible Otto Engine

Patricio Vargas[1], Francisco J. Peña[2], Nathan Myers[3], Natalia Cortes[4,5]

[1]Universidad Santa María (*Physics*) , [2]Universidad Santa María (*Fisica*) , [3]Virginia Tech (*Physics*) , [4]Ohio University (*5Department of Physics and Astronomy, and Nanoscale and Quantum Phenomena*) , [5]Universidad de Tarapacá, (*fisica*)

e-mail: patricio.vargas@usm.cl

Graphene is a remarkable material, belonging to the class of Dirac materials whose electronic structure gives rise to charge carriers that behave as massless fermions, exhibiting relativistic behavior at the laboratory scale. This makes graphene an ideal system for exploring the thermodynamics of relativistic quantum systems. In particular, the energy spectrum of multilayer graphene structures, subjected to an external magnetic field, depends strongly on the number of layers. To investigate the performance of a finite-time endoreversible Otto cycle with multilayer graphene systems as working media, we analyze the engine efficiency as a function of the number of layers. Remarkably, we find that the efficiency at maximum power can exceed that of a classical working medium, with the bilayer system showing the optimal performance. Overall, our results shed new light on the fascinating thermodynamics of graphene multilayers and open up exciting possibilities for its use in advanced technologies.

New 2D materials from non-van der Waals solids

Raphael Tromer[1], Eliézer Fernando Oliveira[2], Cristiano Francisco Woellner[3], Chandra Tiwary[4], Pulickel Ajayan[5], Douglas Soares Galvão[6]

[1]Universidade Estadual de Campinas, [2]Universidade Estadual Paulista, [3]Universidade Federal do Paraná (*Física*) , [4]Indian Institute of Technology Kharagpur, [5]Rice University, [6]Gleb Wataghin Physics Institute, University of Campinas (*Applied Physics*)

e-mail: rrrtremer@gmail.com

The advent of graphene created a revolution in materials science and renewed the interest in new 2D materials. Up to now, most of the 2D structures were obtained from lamellar solids (the so-called van der Waals solids). Because there are no strong bonds among the layers, the structures are easily exfoliated. Recently [1], the first 2D material obtained from non-van der Waals solids (hematene, obtained from hematite) was reported, which opened the perspective to obtain a large number of new 2D materials. Hematite was followed by ilmenite, chromite, magnetite, pyrite, all, 2098mong others [2], as 3D structures used to create new 2D ones. More recently [3], 2D structures from silicates were reported. In this work, we discuss (from theoretical and experimental views) the structural and electronic properties of the new 2D materials, as well as their potential applications as sensors and energy harvesting.

Nothing short of a scientific-industrial revolution is expected from two-dimensional (2D) materials thanks to their exceptional properties that can change paradigms from Engineering to Nanomedicine. In order to become a reality, new accessible 2D materials with different properties will be needed. Therefore, the main focus of the present work is the use of earth-abundant minerals as precursors of new 2D materials.

Our team tackles three main challenges: (1) the prospection of reasonable candidates and their exfoliation mechanisms (focusing on liquid phase exfoliation, which can be scaled up); (2) the characterization and understanding of the physical properties of the new materials (isolated, in heterostructures or composites), using a theoretical-experimental methodology that combines computer simulations with microscopy and spectroscopy technique and (3) the application and validation of the most promising minerals for the production of advanced biomaterials. The theoretical-experimental characterization of the 2D flakes produced (and their possible associations with other materials and molecules) enable the understanding of their new properties and, consequently, the proposal of scientific-industrial applications.

We will illustrate this approach with several examples, from talc to gipsite, including other 2D materials from abundant minerals. In this sense, talc was out first proposal [1] and is the most advanced towards a real-world application as part of an advanced biomaterial [2, 3]. Just like graphene, produced from natural graphite and with a range of spectacular properties different from the precursor mineral, the present work has the potential to add value to abundant minerals and reveal new pillars for the coming revolution.

Among all the 2D materials, graphene is the most studied, it is the first isolated 2D material, and further to its atomically thin structure, it also presents admirable electrical, thermal, and mechanical properties. Those properties motivate using graphene as a membrane in liquid interfaces for applications such as transparent windows, filtering, flow sensing, and DNA sequencing.

A better comprehension of the interactions between graphene/liquid interfaces needs to be improved to enhance the design of applied devices. Raman spectroscopy has a significant role in studying graphene and the interactions between graphene and the surrounding medium, such as substrates, gases, and liquids.

Since Raman spectroscopy is sensible to defects, doping, strain, and strain variations, it can access crucial information about the interaction of graphene/liquid interface.

In this work, we present a microfluidic channel with windows covered with suspended graphene to study the interactions of the air/graphene/air (dry) and air/graphene/water (wet) interfaces. Also, we aim to study the dynamics of the optical response of the graphene when we insert water into the channel and let it spontaneously evaporate.

Our results show that the optical response is sensitive to graphene and water''s mechanical and electronic interactions. As a highlight result, we observe the generation of metastable defects in graphene; those defects increase with time when graphene is in contact with water in the channel.

Finally, we transfer an h-BN flake over a graphene window to understand the difference between this window and the free-suspended membrane; we observe that the h-BN flake makes the graphene sample much more stable mechanically and suppresses some of the interaction signatures.

This study''s results attract a deeper understanding of 2D materials'' interactions with liquids.

Plasmon phonon-polaritons in minimally twisted bilayer graphene and talc heterostructures observed by scanning scattering nearfield optical microscopy

e-mail: tiagocampb@yahoo.com.br

Twisted bilayer graphene (TBG) shows remarkable electronic properties, including superconductivity and correlated insulating states[1]. On electrostatically gated TBG devices with high doping, scattering scanning near field optical microscopy (s-SNOM) reveals triangular domains due to the different optical conductivity of each of the stacking arrangements of the TBG superlattice[2]. In this work, we present a study of plasmon phonon-polaritons in minimally twisted bilayer graphene and talc heterostructures using s-SNOM in the mid-infrared (IR) range without any electrostatic gating. At small twist angles (i.e. angles between 0 and 1.1º), the main part of the triangular domains is constituted by reconstructed regions of stable Bernal (AB or BA) stacking[3], and its boundaries concentrate most of the lattice strain which presents increased optical conductivity[3]. Our experiments were carried out with a mid-IR laser source ranging from 920 cm^{-1}up to 1140 $cm^{-1}$and allowed us to image highly confined plasmon polaritons. In some laser frequencies, we havealso observed sixfold domain wall arrays with the same period as the TBG superlatticewithin the talc reststrahlen band. This work provides new insights into TBG and talc heterostructures electronic and polaritonic properties. We believe our findings will stimulate further research on designing and characterizing novel heterostructures for electronic and optoelectronic applications.

The transition metal dichalcogenide (TMD) family of semiconducting 2D materials present remarkable many-body effects such as an exciton Mott transition into electron-hole plasma (EHP) and liquid phases due to their strong Coulomb interactions. However, the light emission in these high carrier density fermionic phases were only investigated at specific conditions that involved suspended samples with large carrier lifetimes or low temperatures. Here, we show that pulsed laser excitation at high pump fluences can generate this EHP phase in as-exfoliated mono and multilayer TMDs ($WSe_2$and $MoSe_2$) at room temperature leading to a large broadening in their photoluminescence [1]. Besides, these high excitation densities induced an indirect-to-direct band gap renormalization in the multilayer WSe_2samples provoking a notable enhancement in their light emission. In agreement with our theoretical calculations, the EHP photoluminescence at high energies displayed an exponential decay that directly reflected the electronic temperature. Moreover, we probed the dynamics of the EHP by two-pulse excitation correlation measurements and we revealed an ultrafast response of less than 100 fs and a slower one of few ps associated with the electron-phonon and phonon-lattice thermalizations, respectively. Our work may shed light on the study of further many body phenomena at high excitation densities in 2D materials and their heterostructures as well as on novel applications of TMDs in optoelectronic devices.

Spin-valley physics in strained transition metal dichalcogenides monolayers

PAULO EDUARDO DE FARIA JUNIOR[1]

[1]Universität Regensburg

e-mail: fariajunior.pe@gmail.com

Transition metal dichalcogenides (TMDCs) are ideal candidates to explore the manifestation of spin-valley physics under external stimuli. Here, we investigate the influenceof strain on the spin, orbital angular momenta, and g-factors of monolayer TMDCs within first principles[1]. Our calculations reveal the behavior of direct exciton g-factors under the isolated impact of strain: tensile (compressive) strain increases (decreases) the absolute value of g-factors. Strain variations in the range of ±0.5% modify the bright (A and B) exciton g-factors by 0.3 (0.2) for W (Mo) based compounds and the dark exciton g-factors by 0.5 (0.3) for W (Mo) compounds, suggesting that strain can be responsible for g-factor fluctuations observed experimentally. We complete our analysis for the Gamma and Q valleys, revealing that the spin degree of freedom dominates over the orbital angular momentum. This fundamental microscopic insight into the role of strain in the spin-valley physics of TMDCs provided crucial information to understand recent experiments on strained MoSe2 [2] and WS2 [3] samples.

e-mail: hiroki@ufu.br

Van der Waals (vdW) systems composed of graphene (G) and hexagonal boron nitride (h-BN) have been extensively investigated, including recent experimental studies on the large-scale synthesis of h-BN on graphene/SiC(0001) templates [2D Materials **5**,025004 (2018)]. Interestingly, their results suggest that besides the vdW epitaxy of h-BN on graphene, confined growth of h-BN monolayers between graphene and SiC(0001) could also take place, leading to h-BN encapsulation. In this work, we have performed a theoretical study, based on first-principles calculations, of G/h-BN heterostructures on SiC(0001), the latter covered by a carbon buffer layer (SiC). Our findings reveal an energetic preference for the encapsulation of h-BN below a single layer of graphene on SiC, viz.: G/h-BN/SiC in the case of bilayer systems and G/h-BN/G/SiC in the case of trilayer systems. Electronic structure calculations show that graphene''s linear energy band dispersion is preserved in the bilayer systems independent of the stacking order, however, the Dirac points lie in different energy positions due to the different electron doping levels of graphene. In the trilayer systems, the n-type doping level of graphene also depends on the stacking order. The electronic band structure of G/h-BN/G/SiC is characterized by two Dirac points, both below the Fermi level, but with different energies, while the other (energetically less stable) systems, G/G/h-BN/ and h-BN/G/G/SiC are characterized by the emergence of parabolic bands near the Fermi level. Additional structural characterizations of these G/h-BN heterostructures on SiC were carried out based on C-1s core-level-shift (CLS) simulations and carbon K-edge X-ray absorption near edge spectroscopy (XANES), with the goal of assisting future experimental spectroscopy in this graphene/h-BN vdW systems.

Structural and optical characterization of some Van der Waals materials: talc, jacutingaite and tilkerodeite

e-mail: raphael.lobato@ufla.br

The possibility to engineer new two-dimensional layered heterostructures to optimize electrical, mechanical, optical and thermal properties of materials of atomic thicknesses opened the necessity to unveil and understand new minerals. Experimental efforts to synthe laboratory analogs of these minerals are valuable due to the fact that in some situations their natural quantities are not sufficient for further characterization and application studies. In this work the materials talc (mineral) [1], jacutingaite and tilkerodeite (synthed)[2,3] are experimentally and theoretically studied by different strategies by using Raman, nano-infrared spectroscopy, and Density Functional Theory. Their structures are understood according to their dimensionalities, with mechanical properties like their lubricity being explored and compared to other known good lubricants like graphite. The phonon modes are studied, being the results fundamental to understand their applications, and on how to engineer their properties with controlled modifications. In the last decade, transition metal dichalcogenides (TMDs) have been intensively synthesized and studied, allowing a direct correlation of their morphological and physical properties. Nevertheless, the full potential for applications of TMDs intrinsically depends ona deeper understanding of defect type and distribution in these materials. Quantifying and identifying defects in TMDs is therefore mandatory to reach state-of-the-art prototypes and functional optoelectronic devices. In this work we synthesize MoSe2 by APCVD using three different temperatures. The resulting samples are then investigated by Raman and photoluminescence (791nm to 816nm, when we increase the synthesis temperature) spectroscopy as well as by Atomic Force Microscopy. Finally, MOSFET devices are made in order to allow a precise measurement of the electrical resistance as a function of the growth temperature. The relation of Raman spectra and defect density1 and synthesis temperature is established, and a comprehensive comparison with electrical conductivity of MoSe2 carried out. In another work, we are studying the PL as a function of He ions bombardment doses and temperature in MoSe2 monolayers. Here we note a decrease in the intensity of the PL with increasing doses, in addition to a redshift and an increase in the intensity of the spectra when we decrease the temperature. These works sheds light into methods for macroscopic quantification of defect density in TMDs, a crucial parameter to tailor technological applications.

Study of glyphosate adsorption on graphene-based substrates: a DFT study

Wanderson Souza Araújo[1], José Rafael Bordin[1], Maurício Jeomar Piotrowski[1]

[1]Universidade Federal de Pelotas (*Departamento de Física*)

e-mail: wandersonsouza392@gmail.com

We face a period in history when half of the world's population faces water scarcity, and soon the second half of the world's population will face water scarcity also - and climate changes are accelerating extreme weather events, such as long periods of drought. The misuse of herbicides worldwide, headed by glyphosate (GLY), causes fauna, flora, and human health problems. Therefore, studies aimed for the GLY detection and/or removal from aquatic environments are of great importance for the future of mankind. Graphene-based nanomaterials are one of the most promising new technologies to remove GLY and other emergent surfactants. In this direction, we combined a potential energy surface exploration, via *ab initio*molecular dynamics simulations in six different graphene-based chemical environments, from pristine to cased with point defects: monovacancy, doping (nitrogen or oxygen), and adatoms (nitrogen or oxygen), with high-level quantum mechanical optimizations based on density functional theory within PBE Exchange-correlation functional with van der Waals corrections and the projector augmented wave method. Our analysis revealed a rich GLY reaction environment, ranging from physisorption in the case of pristine, N-, and O-doped graphene, with adsorption energy intensities (E_{ad}) lower than 1 eV, with large substrate-molecule distances and total magnetic moments null; up to chemisorption in the case of graphene with monovacancy ($E_{ad} \sim 2.5$ eV), presenting a high interaction energy and total magnetic moments around 2 μ_B, bringing typical characteristics of substrate poisoning. We highlight the GLY interaction with N and O adatom substrates, where the GLY molecule picks up the adatom from the substrate, givingrise to different molecular compositions. In short, our work intends to provide an atomic-level picture of the interactions that can govern the carbon-based devices applied in the glyphosate detection/removal.

Substrate-Induced Changes on the Optical Propertiesof Monolayer WS2

Francisco Araujo[1], Francisco Silva[2], Tianyi Zhang[3], Chanjing Zhou[3], Zhong Lin[4], Nestor Perea Lopez[3], SAMUEL FILGUEIRAS RODRIGUES[2], Mauricio Terrones[5], Antonio Gomes Souza Filho[6], Rafael Alencar[7], Bartolomeu Cruz Viana Neto[8]

e-mail: fdiasisva@ifpi.edu.br

Among the most studied semiconducting transition metal dichalcogenides (TMDCs), WS_2showed several advantages in comparison to their counterparts, such as a higher quantum yield, which is an important feature for quantum emission and lasing purposes. We studied transferredmonolayers of WS_2on a drilled Si_3N_4substrate in order to have insights about on how such heterostructure behaves from the Raman and photoluminescence (PL) measurements point of view. Our experimental findings showed that the Si_3N_4substrate influences the optical properties of single-layer WS_2. Beyond that, seeking to shed light on the causes of the PL quenching observed experimentally, we developed density functional theory (DFT) based calculations to study the thermodynamic stability of the heterojunction through quantum molecular dynamics (QMD) simulations as well as the electronic alignment of the energy levels in both materials. Our analysis showed that along with strain, a charge transfer mechanism plays an important role for the PL decrease.

Super-strong optical phonon energy renormalization measured by spatially coherent tip-enhanced Raman spectroscopy in a graphene device

Rafael Battistella Nadas[1], Andreij Gadelha[2,1], Tiago Campolina Barbosa[1,3], Cassiano Rabelo[4], Thiago de Lourenço e Vasconcelos[5], Vitor Monken[1,4], Leonardo Cristiano Campos[1,3], Riichiro Saito[6], Luiz Gustavo Cancado[1], Ado Jorio[1]

e-mail: nadasbrafael@gmail.com

Optical phonon coherence length (Lc) and group velocity (vg) of graphene as a function of Fermi energy are obtained by spatially coherent tip-enhanced Raman spectroscopy (TERS). It is observed that Lc decreases when moving the Fermi energy close to the neutrality point, which is consistent with the concept of the Kohn anomaly within a ballistic transport regime. An unusually large variation of vg, reaching twice the value for the longitudinal acoustic phonon, is observed for the longitudinal optical phonon close to the Brillouin zone center (Γ point). The strength of this phonon energy renormalization, as observed here, might not be observed by any other technique due to the lack of resolution to measure the phonon dispersion near the center of the Brillouin zone and it is much higher than what has been reported in the literature [1].

Acknowledgments: CAPES.

e-mail: danilo.nagaoka@gmail.com

Two-dimensional (2D) materials have been extensively explored for the development of new and sustainable devices. Among other applications, their high surface-to-volume ratio leads to a promising range of catalytic processes. In the family of 2D materials, transition metal dichalcogenides (TMDs), are a class of layered materials with structure MX2 (M = transition metal and X = chalcogen). In this context, niobium disulfide (NbS2) is a less explored TMD with a metallic character. Although it is a superconductor at low-temperatures[1] and demonstrates great potential to be applied as catalyst or co-catalyst for hydrogen evolution reaction[2], only few reports demonstrated the synthesis of few-layer NbS2. However, before applications can be pursued, it is essential to understand the main characteristics of the obtained material and its stability under atmospheric environment. In this work, we conducted a thorough characterization of redox exfoliated NbS2 nanoflakes, relating our findings to their structure and stability in oxygen-rich environment.[3] Structural, morphological and spectroscopic characterization demonstrated different fingerprints associated with distinct oxidation stages and processes. This led us to identify oxide-species and analyse the stability of the redox exfoliated NbS2 nanosheets in air, suggesting the most likely reaction pathways during the NbS2 interaction with oxygen, which agrees with our density-functional theory results. Understanding the stability of layered materials is of paramount importance to target future applications, mainly because the electronic properties of these materials strongly depend on their integrity.

e-mail: vv.machado@ufpr.br

Kaolinite - $Al_2Si_2O_5(OH)_4$ and talc - $Mg_3Si_4O_{10}(OH)_2$ are abundant clay minerals which present layered particles with nanometric thickness and few micrometers in length. Such characteristics make them materials of interest in the stabilization of emulsions with low interfacial tension like in water-in-water emulsions. After characterization of the layered particles by several instrumental techniques, the effect of adding layered particles on water-in-water emulsions formed by aqueous colloidal dispersions of amylopectin (AMP) and xyloglucan (XG) polymers was evaluated macroscopically, by confocal microscopy and by measurements of the apparent contact angle. Due to a similar affinity for both liquids and their relatively larger size, talc particles presented the Pickering effect [1], positioning themselves in the droplet interfacial region. Despite the smaller size of kaolinite particles and their greater wettability by AMP phase than XG one, the same effect was also observed. In both cases, it was not sufficient to stabilize emulsions for long periods, since the difference of densities between the particles and the aqueous phases led to particle sedimentation even when adhered to the droplets, generating a higher particle concentration at the bottom of the droplets and an incomplete coating of the interface. To avoid this effect, emulsions with a third element that promotes the system gelation might be prepared [2].Acknowledgements:This study was financed by CAPES - Finance Code 001, CNPq (FW: 300988/2019-2; RAF: 301172/2016-1; 430451/2018-0; 303312/2019-0) and FINEP. A comprehensive study of degassing effects on BET surface area of graphene oxide

Tamires Martinhão Machado[1], Sandra Marcela Landi[2], Oleksii Kuznetsov[3], Joyce Rodrigues Araujo[4]

[1]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*Divisão de Metrologia de Materiais*) , [2]Instituto Nacional de Metrologia, Qualidade e Tecnologia, [3]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*DIMAT*) , [4]Divisão de Metrologia de Materiais

e-mail: tmartinhao@colaborador.inmetro.gov.br

Graphene oxide (GO) is an amorphous compound consisted in an oxygen groups-containing 2D honeycomb-like carbon structure, of general (non-stoichiometric) composition $C_xH_yO_z$(y= 0.8 and 1.5 to 2.5 C/O ratio). Due to its great mechanical properties, such as large theoretical specific surface area, GO is regarded as promising material for several applications like energy storage and multifunctional composites [1-3]. In order to determine the surface area of the GO sheets by adsorption of a gas using BET method, the degassing process is always accompanied by the heating of the sample. Although graphene and related materials (i.e., GO, rGO) have been studied over the last 40 years, as far as the authors are aware, there is no reports about the degassing effects on the GO structure and surface area. In this work, the influence of the degassing temperature, sample mass and pre-drying process on the surface area of GO were investigated. The GO sample was submitted to degassing at different temperatures: 50 °C, 80 °C, 150 °C, 250 °C and 350 °C (pre-dried andnot pre-dried). The analyzed mass varied in 100 mg, 150 mg and 200 mg. As result, theadsorption measurement was optimized with degassing temperature of 50 °C, sample massof 200 mg and the pre-drying process decreases the degassing time, but this is not a crucialstep to determine BET surface area. In conclusion, the relation between reduction degree vs. degassing temperature vs. surface area could be established.

A molecular dynamics calculation of the structural properties of functionalized graphene nanoscrolls

Pedro de Camargo Mazon[1], Cristiano Francisco Woellner[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: pemazon97@gmail.com

Nanoscrolls are nanosized membranes rolled into a cylindrical shape with a spiral side-view, where this membrane can be any 2D material [1]. In this work we apply molecular dynamics simulations, using reactive and classical force fields [2], to study the structural and thermal stability (up to 1000 K) of nanoscrolls made out of functionalized graphene sheets. The functionalization of the graphene sheet is made with oxygen-based functional groups [3], and we study the relevance of the ratio between carbon and functionalized groups have in the formation and the stability of the nanoscroll. This was elucidated through the calculation of the energy profile of the formation process of the nanoscroll. Our results demonstrate that the nanoscrolls of functionalized graphene are stable at the simulated temperatures.

This paper presents an efficient computational tool developed in MATLAB to evaluate the effective elastic properties of composite materials with periodic microstructures. The basic building block can characterize the microstructure periodicity called a repeating unit cell of 2D periodic material [1]. The effective elastic properties are determined using a numerical homogenization approach based on the Finite-Volume Theory analysis ([2] and [3]). These effective elastic properties are affected by the constituents' architectural arrangements, volume fractions, and stiffness contrast. The computational code can be easily applied for composite with N-phase, including porous material. Numerical examples involving materials with periodic microstructures are analyzed. The results demonstrate the Finite-Volume Theory formulation's performance for evaluating homogenized or effective elastic properties by comparing with results obtained by the finite-element method [4] and analytical solutions presented in the literature.

Anisotropic Hydrogenation Pattern in a new 2D Carbon Allotrope

Caique Campos de Oliveira[1], Matheus Rodrigues de Amorim Medina[1], Douglas Soares Galvão[2], Pedro Alves da Silva Autreto[1]

[1]Universidade Federal do ABC (*CCNH*) , [2]Universidade Estadual de Campinas (***Departamento de Física Aplicada Gleb Wataghin***)

e-mail: caique.campos@aluno.ufabc.edu.br

The discovery of graphene has renewed interest in 2D carbon nanostructures. Specifically, researchers have proposed new structures by combining hexagonal and other polygonal carbon rings. Recently, Bhattacharya and Jana introduced a new 2D carbon allotrope called Tetra-Penta-Deca-Hexagonal graphene (TPDH-Gr), composed of rings with 4, 5, 10, and 6 carbon atoms [1]. This unique topology results in distinct mechanical, electronic, and optical properties, including potential applications in UV protection. As with other 2D carbon allotropes, TPDH-Gr''s physical and chemical properties can be modified through chemical functionalization. However, the hydrogenation dynamics of TPDH-Gr have yet to be explored, even though hydrogenation is a typical method for functionalization typically occurring in experimental synthesis. In this work, we investigated the hydrogenation dynamics of TPDH-Gr and its effects on the electronic structure using DFT and fully atomistic reactive Molecular Dynamics simulations. This methodology has been successfully used in previous research [2]. Our findings indicate that H atoms are mainly incorporated on tetragonal ring sites, resulting in well-defined pentagonal carbon stripes. The hydrogenated structures show narrow band gaps and the presence of Dirac cones, indicating anisotropic transport properties.

e-mail: moisesdvs@outlook.com

3D bioprinting is a promising technique for biomedical applications. When aligned to low temperature, it promotes the development of biomimetic scaffolds for applications in tissue engineering, providing high resolution to the structure and improved mechanical properties [1]. However, in the current context, there are difficulties about the selection of the applied bioinks as well as limitations when the infusion of cells and consequently the construction of tissues [2]. In the present study, GelMA with graphene at different concentrations were synthed at room temperature and at low temperature for biomedical applications to analyze the mechanical properties derived from graphene and when subjected. GelMA was synthed according to the protocol [3]. Subsequently, a solution of GelMA was prepared at different concentrations of graphene. The scaffolds were printed in 3D using an Allevi 2 Bioprinter. (Descrever um pouco dos resultados). The samples were then characterized morphologically, mechanically, and structurally. The results showed that the structures obtained from the GelMA/Grafeno hydrogels produced have potential for applications in tissue engineering.

Controlling Crystal Phase Transition of MoS2 with ion beams

Alexsandro Vieira da Silva[1], Claudio Radtke[1]

[1]Universidade Federal do Rio Grande do Sul (*Departamento de Fisico-Química*)

e-mail: alex.vieira.rs2012@gmail.com

Recently, transition metal dichalcogenides, or simply TMDs, have attracted great attention due to their vast application field [1]. Among these materials, molybdenum disulfide (MoS2),a two-dimensional material with interesting electronic and optical properties, stands out. However, its properties are significantly influenced by both the number of layers formed and its crystalline structure, which can be of two main forms: 2H and 1T [2]. The 2H crystalline form is the most common and stable form of MoS2, being a direct bandgap semiconductor frequently studied for use in electronic devices. The 1T crystalline form of MoS2 presents metallic properties with high electrical conductivity. Due to the importance of controlling such properties and to apply them adequately, investigation of the induction of phase transition control is crucial. Considering all these aspects, the present work investigates the crystal phase transition of MoS2 induced by ion bombardment. Energetic He ions are used to remove sulfur atoms, leading to phase transformation of the crystalline structure. Modifications are tracked by various techniques, such as X-Ray Induced Photoelectron Spectroscopy (XPS), Raman spectroscopy, and Photoluminescence (PL). Results obtained so far have evidenced that phase modification can be induced by ion beams, provided a careful choice of irradiation time and ion species.

Development of 2D materials based on SnS_2 doped with RE^{3+} ions for application in photonics

Ana Carla da Costa[1], Maria Vitória Guidorzi[2], Rogéria Rocha Gonçalves[3,4]

[1]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto da Universidade de São Paulo (*Química*) , [2]Universidade de São Paulo (*Departamento de Química*) , [3]Universidade de São Paulo (*Química*) , [4]Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto da Universidade de São Paulo

e-mail: ana_cda@usp.br

2D materials have been explored due to their photocatalytic properties by reason of their physical and chemical properties. Tin derivatives sulfides can be obtained in different phases as SnS, SnS_2, Sn_2S_3, Sn_3S_4, and Sn_4S_5[1]. $SnS_2$is an n-type semiconductor with hexagonal structure with applications in nanoelectronics, optoelectronics, catalysis and sensors. The introduction of the rare earth ions (RE^{3+}) into the lattice can modify their features and functionality, changing the semiconductor from n-type to p-type [2]. This work reports a hydrothermal synthesis at 180 ºC for 6h of SnS_2materials with and without RE^{3+}, starting from SnCl4.5H2O and thiourea as precursors. From the X-ray diffractogram, the SnS2 phase with a hexagonal structure was identified, with a space group P63mc (JCPDS no. 43003) and cell parameters set as a=53.645 b=3.645 c=11.802. Luminescence and photocatalytic properties are in progress and will be explored to evaluate their potentiality to be applied in photonics as photocatalytic system driven by upconversion and NIR sensors.

Acknowledgments:

We acknowledge FAPESP, CAPES and Cnpq.

Currently, the detection of Carbon Dioxide (CO2) has been a factor of extensive investigation, due to the various problems that this gas can cause to the environment, the health of humans and animals, and the agri-food industry [1]. In this context, the objective of this work is to develop CO2 sensors based on optical fibers of the LPG (Long Period Grating) coated with graphene oxide (GO). The sensors with optical fibers have certain advantages compared to other sensors, such as immunity to electromagnetic interference, compact size, multiplexing capability, easy integration to remote sensing, and high corrosion resistance. LPGs are based on diffraction gratings, i.e., a periodic modulation in the refractive index along with the core of the optical fiber, which is a technique widely used to improve the detection efficiency of optical fibers. LPGs do not have a high sensitivity to CO2 thus, it is necessary to use some coating on their grating to increase their sensitivity for gas detection. Thus, by coating the core of these fibers with GO, it is possible to improve their detection system. Recent studies show that GO has a significantly shorter response time compared to other materials for CO2 detection, at various concentrations and under varying humidity and temperature conditions [2]. One of the factors that contribute to this is the high surface area that this nanomaterial has, which allows a greater biomolecular interaction per unit area and can contribute to the immobilization of gas molecules. We are currently performing preliminary tests with GO-coated LPG for the sensing of various CO2 concentrations.

e-mail: marcosrochadiniz@hotmail.com

Since graphene was discovered in 2004, has attracted the attention of many researchers, due to its outstanding electrical, thermal, and optical properties. Based on that, graphene and its derivatives, have been touted as a candidate for the development of microfibers, due to their superior properties concerning conventional carbon fibers [1]. Previously, we reported the development of graphene derivative microfibers with controlled and homogeneous shapes and tunable diameters, fabricated exploring the 3 dimensional (3D) hydrodynamic focusing concept on a microfluidic device [2]. However, there is still room for improving the mechanical properties of neat graphene derivatives microfibers. One interesting approach consists of the use of molecular-like materials that can act as a bridge between the GO nanosheets, improving the binding between them. In this way, we address an optimization study of the incorporation of carbon nanotubes (CNTs) on GO dispersion, aiming for the preparation of graphene derivative fibers with superior mechanical properties. The GO sheets were obtained by modified Hummer´s method [3] and characterized by Raman spectroscopy. We investigate the effect of mild oxidation of single-walled carbon nanotubes (SWCNTs) and multi-walled carbon nanotubes (MWCNTs) to obtain stable aqueous dispersion. For this, we performed the procedure described by Rosca et al [4], followed by the sonication in ultrasound tip and ultrasound bath at a frequency of 24 Hz and power of 280 W in 0.5 cycles for one hour and twenty minutes. It was possible to obtain stable CNTs dispersion by the low insertion of oxygen functional groups. We evaluated the effect of the incorporation of the aqueous dispersion of 1 mg/mL SWCNTs ox. and MWCNTs ox. in the GO dispersion (5 mg/mL) pointing to the preparation of GO microfibers, using a CTAB 0,05%. We obtained GO fibers longer than 5 cm. We demonstrated a systematic study of the fabrication of hybrid CNTs ox - GO fibers by wet-spinning.

Development of Inexpensive Laser-Induced Graphene Sensors for Electrochemical Detection of NADH

The use of graphene-based materials in electrochemical sensing has gained significant interest due to their unique properties, such as high surface area, conductivity and electrocatalytic behavior [1]. Among these materials, Laser-Induced Graphene (LIG) has become increasingly popular. LIG can be fabricated on flexible substrates using a fast and simple laser irradiation process, making it an attractive option for electrochemical sensor development. In this study, a low-cost electrochemical sensor was fabricated using LIG for the detection of nicotinamide adenine dinucleotide (NADH) at a low potential of 50 mV vs Ag/AgCl. The LIG was produced using mild laser power conditions (1.5 W laser power at 405 nm) on a polyimide substrate, resulting in electrically conductive graphene with a sheet resistance of 24.38 ± 2.19 Ω/□ and a porous 3D morphology rich in defects. Pseudo-reference electrodes based on Ag/AgCl were obtained by a simple chlorination approach on a deposited silver layer, resulting in a stable potential with a potential difference of less than 2.5 mV vs Ag/AgCl (3 mol L^{-1}KCl) commercial electrode. The electrochemical LIG-based sensors were then used to detect NADH, an essential coenzyme for neurotransmitter activities, with a linear range of 0.05-10 mmol L^{-1}. The presence of residual oxygenated functional groups (C-O/C=O) on the LIG structure was found to be essential for the electrocatalytic activity towards the electrooxidation of NADH at low potential [2]. Overall, the electrochemical LIG-based sensors show promise in the development of biosensors for the sensitive detection of pathogens, such as bacteria.

e-mail: d.losito@unifesp.br

Cerium oxide-based nanocomposites are an attractive option for use in environmental catalysis applications due to their unique structural, textural, and morphological properties. To create promising materials for use in this field, researchers have investigated the development of nanocomposites containing CeO2 and SBA-15 as a support for catalytic metals (CM), including both noble (Pd, Pt and Rh) and non-noble (Ni and Co) metal-based catalysts. The incorporation of CeO2 enhances the catalytic activity by promoting the dispersion of CM in the mesoporous structure of SBA-15, thus avoiding agglomeration, and providing better interaction between the metal-support. Additionally, SBA-15 increases the thermal stability of the CM, preventing sintering. To prepare such support materials, CeO2 precursor salt (Ce(NO3)3.6H2O) was incorporated in SBA-15 using the direct synthesis method. Imidazolium-based ionic liquids (ILs) with different alkyl chains and anions (Br- and BF4-) were employed as a reaction medium to study the effect the salts in the preparation of the mentioned nanocomposites. The SAXS curves revealed that all nanocomposites have a 2D hexagonal mesostructured characteristic of SBA-15. The DRX analysis confirmed the crystalline cubic fluorite-type of space group Fm3m structure of CeO2, as also observed by Raman spectroscopy. The surface area (BET), was found to be lower for the nanocomposites prepared with the IL with BF4- anion. However, these nanocomposites had a higher average pore diameter when compared to the ones prepared with Br- anion. SEM images were used to visualize the morphology and particle size of the material, which was found to be influenced by the used IL. The researchers comparatively studied the structural, textural, and morphological properties of the materials, and found that the IL anion hydrophobicity influences the mesophase, leading to larger pores.

Electrochemically reduced graphene oxide onto flexible interdigitated electrodes as strain sensors

Thyago Santos Braga[1], Isadora Bernardes Sequalini[1], Thiago Teixeira da Silva[1], Evaldo Jose Corat[2], Nirton Cristi Silva Vieira[1]

[1]Universidade Federal de São Paulo, [2]Instituto Nacional de Pesquisas Espaciais

e-mail: thyago.braga@unifesp.br

Graphene oxide (GO) is a graphene derivative obtained cheaply by the Hummers'' method. It is an electrical insulator that becomes a good conductor when subjected to a reduction treatment (usually chemical or thermal). This study presents the electrochemical reduction of GO to rGO (reduced graphene oxide) directly onto flexible interdigitated gold electrodes and its application as strain sensors. The ultimate goal is the development of sensors using electrochemical reduction alternatively to thermal and chemical reduction routes, which use dangerous reagents or a large amount of energy. Therefore, the GO reduction was performed using cyclic voltammetry (-1.5 V to 0 V and 0 to -1.5 V), and it was found that only one cycle is necessary to reduce the GO to rGO with low resistance (<100 Ω). A typical graphene-like behavior was confirmed when the devices were applied as electrolyte-gated field-effect transistors. As strain sensors, rGO onto flexible interdigitated gold electrodes presented a GF (gauge factor) average of 3.4, a value ca. 60 % higher than conventional metallic strain sensors. Acknowledgement Fapesp process 18/07508-3.

Electronic properties of MoS_2 modified by Ionic Liquid functionalization

e-mail: lidipluc@hotmail.com

The unmatchable properties of two-dimensional (2D) layered transition-metal dichalcogenides (TMDs) have been drawing appreciable attention. Varying TMD's composition allows to tune band gaps between 0 to 2 eV. Such versatility allows their use as metal or semiconductor materials. Furthermore, monolayer TMD'S exhibit a direct band gap allowing their use in optoelectronic devices. In order to take advantage of all these properties, and enhance some features, functionalization of different sources are vastly studied. Photoluminescense (PL) enhacement or quenching is intrinsically related not only to material layer's numbers, as also to the functionalizing molecules. PL also shows different responses depending on the solvent used on solution preparation. In our investigation, $MoS_2$was synthed by sulfurization of sodium molybdate. An aqueous solution of this salt was spin coated on the surface of a silicon substrate. Following the sulfurization step, $MoS_2$was obtained in most of the sample surface. Functionalization with two distinct ionic liquids were performed by drop deposition. We used 3-butyl-1-methyl-1Himidazol- 3-ium bis((trifluoromethyl)sulfonyl)amide which is highly hydrophobic and 1-Butyl-3-methylimidazolium hexafluorophosphate both diluted in dichloromethane. XPS, Raman, and PL results indicate functionalization of MoS_2in addition to modification of its electronic properties seen by differences in PL results.

Evaluation of electrical and electromagnetic propertiesin PC/ABS blends-based graphene nanoplatelets and carbon nanotubes nanocomposites

Erick Gabriel Ribeiro dos Anjos[1], Eduardo Antonelli[1], Mirabel Cerqueira Rezende[1], Fabio Roberto Passador[1]

[1]Universidade Federal de São Paulo (*Departamento de Ciência e Tecnologia*)

e-mail: erickgabsjc@gmail.com

Polycarbonate (PC)/acrylonitrile-butadyene-styrene copolymer (ABS) blends are commonly applied in portable electronics. For this application, some polymer parts need addition of metallic components, or a posterior metallization process, to promote electromagnetic compatibility (EMC) of the electronic enclosures. An alternative way to improve the EMC in PC/ABS blends is the addition of conductive fillers as graphene nanoplatelets (GNP) and multi-wall carbon nanotubes (MWCNT) [1-2]. In this work, PC/ABS blends (85/15) with the addition of 3 wt% of GNP (MGgrafeno, Brazil) and 1.5 and 2 wt% of MWCNT (NC7000, Belgium) were prepared in a twin screw extruder (AX Plásticos, model AX16:40DR). Specimens were prepared by injection molding (Battenfeld, model Plus 350/75). The nanocomposites were characterized by Field Emission Gun Scanning Electron Microscopy (FEG-SEM, TESCAN - MIRA3), impedance spectroscopy (Impedance/Gain-phase Analyzer, model Solartron SI 1260) and the electromagnetic interference shielding (EMI SE) in the X-band (8.2-12.4 GHz) were measured in a vector network analyzer (VNA, Agilent Technologies, model PNA-L N5235A) with a coupled waveguide (WR-90). The injection molding process interferes in the formation of the morphology, since it can favor the orientation of the GNP in the direction of the molding flow, hindering or even destroying the ideal three-dimensional formation. The addition of 3 wt% of GNP promotes a total attenuation (SET) of 5 dB. The addition of 1.5 or 2 wt% of MWCNT in the PC/ABS/GNP composition promote a sinergistic effect with the increase the SET values for 19-20 dB. These hybrid nanocomposites are a promising material for future EMI SE applications with a more substantial attenuation.

Graphene is a two-dimensional material formed by carbon atoms in a hexagonal lattice. This carbon allotrope is known for its interesting properties, such as mechanical strength and high electrical and thermal conductivity [1]. Moreover, graphene and its derivates is also exploited for biomedical applications due to their ability of absorbing NIR light and transforming it into local heat. Normally, graphene sheets have micrometric scale, which can be a limiting factor on cellular internalization. Hence, in this work, we studied the effect of the photothermal activity of several sizes of reduced graphene oxide sheets aiming a better proportion between size and its ability on converting NIR radiation. For that matter, graphite flakes were oxidized following a procedure described in literature, producing graphite oxide (GO) [2]. Thus, six GO dispersions were prepared and exfoliated at different times, using either an ultrasonic bath, at frequency of 40 kHz (2 h, 4 h and 6 h) or a probe sonication, at a frequency of 20 kHz (30 min, 1 h and 2 h) [3]. The resulting dispersions were then lyophilized. The following steps include i) Raman spectroscopy characterizations, in order to evaluate defects degrees after the exfoliations processe ii) scanning electronic microscopy (SEM) to determinate a size distribution and iii) evaluate the photothermal activity ofthe chemical reduced form of GO (rGO) by irradiating the materials with a red laser, varying the dispersion concentration.

In 2D materials-based heterostructures, the dynamic strain and piezoelectric potential modulation carried by the SAW strongly interact with optically generated electron-hole pairs. In this contribution, we investigate the acoustically modulated charge and exciton dynamics in WSe2 monolayers (1L) encapsulated in hexagonal boron nitride (hBN) layers onto LiNbO3 substrates. Below 200K, we show that the exciton dynamics can be efficiently modulated by the SAW with very fast on and off times. Quenching of the photoluminescence (PL) emission, which can be controlled with the acoustic power, is attributed to the effective interaction of the excitons and the SAW piezoelectric field [1,2]. We also generate standing wave patterns on the sample surface, demonstrating carrier localization in the wave antinodes. At room temperature (295K), the exciton dynamics under acoustic waves is clearly affected by the presence of extra charge carriers introduced in the overall dynamics. These carriers may be optically injected from the substrate [3] or from traps associated with defects or potential fluctuations in the hBN/1L-WSe2/hBN heterostructure. As the SAW power is increased, the extra carrier density leads to an initial gain in photoluminescence emission, due to screening of the SAW piezoelectric field, followed by an overall PL quenching at higher acoustic powers. Therefore, we observe two different carrier transport regimes which may help us to find more effective means to manipulate fundamental excitations in 2D transition metal dichalcogenides systems.

e-mail: maryyk025@gmail.com

The search for a more sustainable energy matrix has been an urgent topic in science, and the use of Hydrogen presents itself as an interesting alternative. The challenge of implementing this technology lies in the lack of a stable catalyst, with high catalytic density and composed of materials abundant on Earth. In this context, two-dimensional materials, such as Molybdenum Disulfide (MoS2) and its heterostructures, may present catalytic activity for the Hydrogen Evolution Reaction (HER). However, this activity is concentratedat the edges and defects of the material.

To modify these characteristics, it is possible to add a conductor material or a dopant that activates the basal plane of MoS2, increasing its conductivity and catalytic activity. We used Graphene Oxide (GO) to build a heterostructure where GO and MoS2 films are stacked. To produce this heterostructure, a 2^3 factorial design was used, which consists of a variation of synthesis conditions such as temperature, compound concentration, and synthesis time.

Using Ammonium Tetrathiomolybdate ((NH4)2MoS4) precursor, which was diluted in water and mixed with GO solution and deposited on SiO2 substrates, it was taken to the oven for thermal decomposition of the reagents. The results were evaluated through Optical Microscopy, Atomic Force Microscopy (AFM), and Raman Spectroscopy to analyze the surface of the samples and layer composition.

Acknowledgements: We would like to thank Serapilheira for the scholarship.

GRAPHENE OXIDE NANOFLUIDS FOR ENHANCED OIL RECOVERY (EOR)

KELLY CRISTINA BASTOS MAIA[1], Arley Sena do Nascimento [1], Giulia Castro da Cruz[1], Agatha Densy dos Santos Francisco [1], Daniel Grasseschi[1]

[1]Universidade Federal do Rio de Janeiro (*Departamento de Química Inorgânica*)

e-mail: kellymaia.quim@gmail.com

Chemical methods used for enhanced oil recovery (EOR) are based on reducing interfacial tension, improving sweeping efficiency, and reversing rock wettability to increase oil displacement in the reservoir. Graphene oxide (GO) based nanofluids have the potential to be effective EOR additives due to their ability to affect the physicochemical properties of fluid-fluid and rock-fluid systems. The oxygenated groups on the surface of GO provide stability in aqueous medium and potential sites for chemical modification to improve stability and effectiveness. While surfactant injection is commonly used in EOR, it can present problems such as loss by adsorption and instability under adverse salinity and pressure conditions. In this study, we evaluate the use of GO in different degrees of oxidation as a carrier for surfactant nanofluids in EOR. The GO is characterized by SEM and AFM, FTIR, and Raman to determine its structural and morphological properties. Zeta potential measurements are used to assess the colloidal stability of GO under various conditions. Wettability is evaluated by measuring the contact angle of calcite fragments aged in crude oil and fragments treated with the nanofluid. The performance of GO-based nanofluids and the combined system GO@surfactant in EOR is evaluated using tests on finely divided limestone in unconsolidated porous medium. Dynamic transport and oil displacement tests are used to assess the systems'' applicability as EOR additives.Acknowledgments: CNPq / Fundação Capes / Petrobras.References:[1] SIKIRU S, Rostami A, Soleimani H, et al. The BiI3-Graphene 2D material was obtained by physical vapor deposition in a specialized equipment designed to operate under pressure conditions of 10-7-10-8 mBar, which allowed for strict control of variables such as source and substrate temperature, deposition time, and source-substrate distance. BiI3 was grown onto both graphene-covered TEM grids and single layer graphene SiO2/Si substrates, previously ozone-treated. The growth conditions included a source temperature of 265 ± 1°C, substrate temperature of 40 ± 1°C, depositiontime of 30-120 s, source-substrate distance of 20.0 ± 0.5 mm, and a high-purity Argon atmosphere. The resulting 2D material layers were characterized using High ResolutionTransmission Electron Microscopy (HR-TEM) and Energy Dispersive Spectroscopy (EDS) forgrids, and X-Ray Reflectometry (XRR) and Gracing Incidence X-Ray Diffraction (GIXRD) forsubstrates.The layers of BiI3 exhibited a rotation between them, resulting in a Moiré effectindicating the presence of BiI3-Van der Waals superstructures within two or three BiI3 layers. The majority of the surface was covered, although not uniformly. Fast Fourier Transforms (FFTs) indicated that the orientation of the layers was always with the c-axisperpendicular to the grid substrate, in its rhombohedral phase R-3. GIXRD confirmed thelayer composition as BiI3 growth onto single layer graphene SiO2/Si substrates, in agreement with EDS and HR-TEM results, and the orientation of the BiI3 layers with the c-axis perpendicular to the substrate, which also agrees with HR-TEM results. The BiI3 layerexhibited a density of around 6.0 g/cm3, a thickness of 34.6 nm, and a roughness of 6.0nm.In the future, it is proposed to perform solar simulation tests to evaluate the potentialphotovoltaic applications of the material.

Investigating Raman scattering of MoS2 monolayer onAu Plasmonic Grating.

Two-dimensional transition metal dichalcogenides (2D-TMDCs) have attracted attention because of their unique properties compared to their bulk counterparts [1], which make them ideal candidates for optoelectronic devices [2]. MoS2 monolayer (ML) is an example of 2D-TMDCs compound, considered one of this family''s most stable layered materials [1]. It is an inorganic semiconductor with a direct gap and high photoluminescence (PL) emission, where the optical response is primarily determined by excitonic transitions [1]. In addition, MoS2 ML exhibits only three zone-center first-order Raman active modes [3]. It is also possible to observe second-order bands, depending on the energy of excitation [4]. In this study, we investigated the vibrational properties of MoS2 ML deposited on different fabricated Au gratings (GR) - square and circular geometries. These GR are composed of long sub-wavelength slits with a width of 100 nm, separated by varying distances in the nanometer range. We examined the MoS2 ML on both supported and suspended regions inside the GR using confocal μ-Raman spectroscopy. Our results showed that the out-of-plane mode was more intense in the suspended regions than in the supported ones for all geometries. Additionally, we verified that a broad band around 450 cm-1 associated with second-order effects was more pronounced in the suspended regions. Moreover, we observed the Raman modes enhancement due to the plasmonic field in the suspended region and depended on the GR parameters. In conclusion, our results demonstrate a dependent relationship between the vibrational lattice properties and the characteristics of the Au plasmonic GR.

Investigating the Electronic Properties of Strained Biphenylene-Based Structures through the DFTB Method

Marcelo Alves Ferreira[1], Cristiano Francisco Woellner[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: marceloaf98@hotmail.com

In 1941 a novel organic compound known as the biphenylene molecule, a hydrocarbon compound consisting of two six-membered aromatic rings separated by a four-membered ring, was proposed by W. C. Lothrop[1]. When connected to form a network, carbon octagons are formed between two biphenylene molecules. Due to recent developments in materials research, the biphenylene network has become a promising allotrope of sp^2-hybridized carbon atoms, distinct from graphene sheets, as it exhibits different electronic properties[2]. The synthesis of a biphenylene network (BPN), was recently achieved[2] through an on-surface interpolymer dehydrofluorination (HF-zipping) reaction. This allotrope presents many possible applications in the field of materials. Our study focuses on examining the effects of strain on its electronic properties, including density of states (DOS), band structure, and energy gap. Our main goal was to evaluate the BPN' s electronictunability by applying strain and whether it remains metallic thereafter. We have also obtained mechanical properties such as its Young' s modulus and concluded that it has a brittle nature, given that it loses its integrity after a certain amount of strain is applied. Toachieve this, we used the DFTB+[3] software to implement the DFTB method for our simulations and discovered that the results yield a metallic behavior for the BPN. As strainis applied, the system begins to show a Dirac point in the Fermi energy, while still maintaining its metallic properties.

Investigating the Mechanical Behavior of Molecular Kirigamis of WSe2 using Molecular Dynamics Simulations

Erick Dos Santos Morais[1], Marcelo Lopes Pereira Júnior[2], Luiz Antônio Ribeiro Júnior[1]

[1]Universidade de Brasília (*Institute of Physics*) , [2]Universidade de Brasília (*Faculty of Technology Department of Electrical Engineering*)

e-mail: 221010407@aluno.unb.br

Transition metal dichalcogenidesis study, we investigate the mechanical behavior of molecular kirigamis of WSe2 using molecular dynamics simulations with the LAMMPS software [1] and the reax force field [2]. Kirigami is a process of creating new patterns and shapes by cutting, stretching, or twisting materials. In molecular systems, kirigamis can be generated by manipulating the atomic structure of a material to create new molecular arrangements. Our study focuses on investigating the behavior of molecular kirigamis of WSe2 and their impact on the material''s fracture patterns and elastic properties. To minimize modeling stresses, we equilibrate the system with the NPT ensemble for 100 ps and then apply uniaxial tension with the NVT ensemble at 300 K. We simulate the temporal evolution of atoms and molecules in the system using the Newton equations of motion and the Velocity-Verlet algorithm. Similar studies have been conducted on kirigamis of graphene and MoS2 [3], and this work builds on these previous findings to investigate WSe2. Our findings contribute to the fundamental understanding of WSe2, open up new avenues for material science research and emphas the importance of utilizing advanced computational methods to investigate the properties of materials.

Layered double hydroxides for immobilization ofhazardous wastes

Tiago Kalil Cortinhas Alves[1], Leonardo Boiadeiro Ayres Negrão[2], Stefan Stöber[1] [1]Martin

Luther Universität Halle Wittenberg (*Mineralogy*) , [2]Malvern Panalytical, a division of Spectris do Brasil

e-mail: tiago.cortinhas-alves@geo.uni-halle.de

Cementation is a widespread and consolidate technology used to immobilize diverse types of hazardous materials in a stable cement-matrix avoiding its release into the environment. Recently, many low molecular weight organic admixtures are being employed to improve the physical properties of this matrix. During the cementation process toxic oxyanions are intercalated and immobilized in AFm-phases. AFm-phases refer to the family of two-dimensional layered double hydroxides (LDH) and are formed during hydration and curing of cement. The goal of this study is the pure synthesis and precise characterization of solid solution formation between small organic molecules (from non-corrosive accelerators of cement) and inorganic toxic oxyanions like CrO_4^{-2}. Stoichiometric amounts of CaO, $CaAl_2O_4$, $CaCrO_4$and decarbonated water were mixed at a W/C =10 with $Ca(HCOO)_2$at 25°C to investigate the formation of different LDH at different relative humidities. The experiments were conducted in a glove box under the Ar atmosphere to avoid carbonation. X-ray powder diffraction, SEM-EDS, thermal analysis, Raman, IR-spectroscopy and Ion chromatography(IC) were used in order to characterize the hydrated compounds. The X-ray diffraction patterns of $CrO_4^{-2}/(HCOO)_2^{-2}$-containing mixtures show well crystallized AFm-phases with trigonal/hexagonal or monoclinic structures varying with increasing HCOO-concentration. A Pawley fit was performed to determine the lattice parameters of the synthesized compounds and using a combination of EDS/IC the composition of the samples was determined. The spectroscopic measurements confirm the intercalation of $CrO_4^{-2}/(HCOO)_2^{-2}$into the interlayer of the synthesized LDHs. Scanning electron microscopic analysis shows that the morphology of the synthesized samples varies as a function of $HCOO^-$concentration.

Low-Temperature Treatment of Graphene Oxide Dispersions: Implications on its Optical and Electrical Properties

e-mail: camilattavares15@gmail.com

The excellent physicochemical properties exhibited by carbon nanomaterials, such as high electrical conductivity, good optical transmittance, and exceptional flexibility, make them a major topic of research due to their wide-ranging possibilities for applications in various areas. Among them, graphene oxide (GO) is a two-dimension carbon nanomaterial with hybridization sp2/sp3 and the nanosheets have different oxygenated functional groups randomly distributed, for example, carbonyl (C=O), hydroxyl (C-OH), carboxylic acids (HO-C=O) and epoxy (C-O-C). The presence of oxygenated groups indicates that this material is oxidized and it becomes possible dispersion of the material in water. In this work, the synthesis of different types of graphene oxide was made and aqueous dispersions of these materials were kept under thermal treatment at 80°C for seven days to study the effect ofthe diffusion of oxygenated groups through the plane of the material. This phenomenon previously reported in a paper [1] and little experimentally explored until now. All dispersions were characterized using ultraviolet-visible absorption spectroscopy (UV-VIS). The optical bandgap was determined from the UV-Vis spectra and the results showed that with the passing of the days, a reduction in the bandgap value occurred for all samples. Furthermore, thin films were fabricated using these dispersions, the Hall effect technique analyzed the electrical properties and showed a reduction in the value of sheet resistance for GOs that were subject to temperature. The results indicated that the phenomenon of diffusion is dependent of GO stoichiometric and degree of exfoliation and for this some oxygenated groups are more likely to diffuse in the GO structure and this is in good agreement with the theoretical predictions.

Acknowledgments: The authors thank CAPES, CNPq and FAPEMIG for funding this work.

Magnetic properties of open shell element dopedsilicene

Lucca Moraes Gomes[1], Andreia Luisa da Rosa[1], André Felipe Pereira de Oliveira[1], Flávio Bento de Oliveira[1]

[1]Universidade Federal de Goiás (*Instituto de Física*)

e-mail: luccanok@discente.ufg.br

The growing interest in low-dimensional materials led to the emergence of important ramifications in scientific knowledge, such as the emergence of nanoscience and nanotechnology. Materials at the nanometric scale present different behaviors from those ofa macroscopic structure. Due to associated quantum effects, these materials may have new properties such as high electronic mobility and thermal conductivity, in addition to greater mechanical strength. On the other hand, silicon is a material whose technological application is well established, and obtaining this material in nanostructured form increases its possibility of integration in current technology. Doping with open layer elements can be used to adjust the band gap of silicene and at the same time introduce new functions, such as making the material ferromagnetic. However, several aspects of silicene doping with transition metals still remain unanswered, such as dopant solubility limits, site preference for adsorption and doping, and formation of magnetic domains. The direction of adsorptionof the chromium atom on the silicon monolayer was also investigated, the silicene bilayerwas also investigated with different types of stacking, the doping was done in order to position the chromium atom between the two sheets. In this work we carry out the investigation of diffusion doping of Chromium atoms on silicene. We verified that some metals introduce new magnetic properties in silicene, in addition to forming metallic alloyswith it, which is promising for the application of these materials in electronic and magneticdevices.

Mapping defects in WS_2 monolayers doped withVanadium by Linear and Non-Linear Optics

Two-dimensional (2D) materials have proven to be very relevant in basic research and technological applications since the discovery of graphene almost two decades ago. Other families of 2D materials, in particular Transition Metal Dichalcogenides (TMD), have different electronic and vibrational properties than graphene and therefore allow us to formulate new technological applications. For example, it has recently been shown that a two-dimensional semiconductor can be transformed into a ferromagnetic material at room temperature (300 K) with the introduction of outer transition metal atoms as dopants [1]. The objective of this work is to study how the addition of these dopants changes the optical and structural properties of these 2D materials. To this end, we use nonlinear optics techniques such as Four Wave Mixing (FWM) in conjunction with linear optical techniques (Raman Spectroscopy and Photoluminescence) to study samples of Tungsten Disulfide (WS_2) doped with different concentrations of Vanadium. The PL spectrum of the doped samples showed two peaks, excitons $A$and $A*$, the last present in the samples with the introduction of Vanadium. Resonant FWM images with exciton $A*$reveal distinct intensities throughout the sample, possibly showing that the introduction of defects is inhomogeneous and concentrated in lines connecting the center to the vertex of the triangular WS2 flakes. The Raman Spectroscopy results also show changes in the vibration frequencies of E_{2g}modes along these lines indicating an increased presence of Vanadium related defects, showing that the introduction of Vanadium is not homogeneous throughout the sample, hence improvements in the growth of these samples need to be made for future technological applications of these compounds.

Ultrafast optical pump-probe is a well know and powerful tool for studying excited-state dynamics in material' s science. In such an experiment, the pump pulse is responsible for creating an out-of-equilibrium configuration in the sample, e.g., exciting carriers to higher energy levels and elevating the local temperature. By detecting the probe pulse, which is delayed back with respect to the pump pulse, we can relate the changes in its transmitted intensity, i.e., transient absorption (TA), with the carrier''s dynamics in our sample. In graphene, the processes induced by the pump pulse can be divided in three parts: I) excitation of electrons, which occurs in a femtosecond scale; II) cooling of these hot electrons creating hot optical phonons (~ 1-2 ps); and III) anharmonic decay of optical phonons into acoustic phonons, which are responsible for the dissipation of heat between the graphene and the substrate, having a much longer lifetime decay (~ 100 ps).[1]Here, by combining optical pump-probe with a laser scanning system, we performed a spatial and temporal resolved pump-probe microscopy in graphene over silicon dioxide (SiO_2) and boron nitride (BN). By measuring the longer lifetime related with heat dissipation of graphene to the substrate, we were able to determine the interfacial thermal conductance of graphene with these substrates and its spatial variation. Our work opens opportunities for testing the heat dissipation of graphene on different substrates and to engineer more sophisticated heterostructures for heat management on future electronic devices.

e-mail: flavioferrs@gmail.com

Surface plasmon-polaritons (SPP), quasi-particles originated from the coupling of photons to collective oscillations of free charge carries, are intrinsically two-dimensional (2D) modes of the interface between a material with metallic character and a dielectric insulator. In the technologically attractive mid-infrared (IR) range, SPPs can access and retrieve information from interface states associated to molecular vibrations, electronic transitions of energy around 50 - 300 meV and room temperature thermodynamical reactions. But, in analogy to free space waves or propagating optical modes in fibers, the use of SPPs as information carriers is critically dependent on their propagative properties in media supporting mid-IR plasmonic waves. Despite semiconducting and metallic micro- and nanostructures can bear stationary and localized SPPs enabling functionalities as antennas and resonators in the mid-IR, these media are reported to have high ohmic losses that hamper the efficiency of propagative modes. As a promising alternative, we present here the first real-space, nanoscale resolved imaging/spectroscopy of micrometer-d wavelength SPP waves in insulator/metal/insulator (IMI) heterostructures with propagation lengths exceeding 20 μmat room temperature in the 750-1450 cm^(-1) mid-IR range. Our theory predicts SPP group velocities reaching 20 % of the light velocity in vacuum and 0.2 - 0.4 ps lifetimes. We further demonstrate that the SPP waves interact with polar crystals phonons in the strong coupling regime. As a general effect of the metal/dielectric interface, the mid-IR SPP waves can be compelling for fast metal-based plasmonics, whilst their ability to strongly couple to phonons can be further explored for enhanced sensing in the mid-IR.

Optical Characterization of Vanadium Doped WS_2 Monolayers with Room-Temperature Ferromagnetic Ordering

Frederico Barros de Sousa[1], Mingzu Liu[2], Boyang Zheng[2], Geovani C. Resende[3], Felipe Menescal Pinto de Medeiros[4], Marcos A Pimenta[3], Vincent Crespi[2], Mauricio Terrones[2], Leandro M. Malard[4]

The defect engineering of 2D transition metal dichalcogenides (TMDs) has been widely explored in order to tune the properties of these materials and thus expand their applications. For instance, dilute magnetic semiconductors have been achieved by the introduction of spin-polarized transition metal atoms as substitutional defects in TMDs. A long-range ferromagnetic ordering even above room temperature in vanadium doped WS_2 [1] and WSe_2samples was recently reported, shedding light on the large possibilities for spintronic devices fabrication. Hence, the characterization of the optical and electronic properties of these V doped TMD monolayers as well as the understanding of their mechanism of magnetization become crucial. In this work, we have combined both theory and different experimental linear and nonlinear optical techniques to probe the changes in the electronic structure of WS_2monolayers with increasing vanadium doping concentration. Density functional theory band structure calculations showed a down shifting of the Fermi level inside the valence band for the doped samples and the emergence of an occupied V flat band. Power dependent photoluminescence and four-wave mixing resonant profiles revealed the presence of free holes in the valence band edge and a major role of the V flat band in the optical transitions close to the A exciton energy. Moreover, resonant Raman spectroscopy were performed and displayed a blueshfit in the B exciton energy under increasing V doping, while resonant second-harmonic generation measurements showed no modification in the C exciton energy. Besides that wide optical characterization, our experimental results corroborated by the theoretical calculations indicate an indirect mechanism of magnetization for these V doped WS_2monolayers. Furthermore, our work reinforce the potential of distinct optical tools to probe defects in 2D materials.

In recent years, an unconventional excitation of trivalent neodymium ions (Nd^{3+}) at 1064 nm, not resonant with ground-state transitions, has been investigated with the unprecedented demonstration of a photon-avalanche-like (PA-like) mechanism, in which the temperature increase plays a fundamental role. As a proof-of-concept, $NdAl_3(BO_3)_4$ particles were used. A consequence of the PA-like mechanism is the absorption enhancement of excitation photons providing light emission at a broad range covering the visible and near-infrared spectra. In the first study, the temperature increase was due to intrinsic nonradiative relaxations from the Nd^{3+} and the PA-like mechanism ensued at a given excitation power threshold (Pth). Subsequently, an external heating source was used to trigger the PA-like mechanism while keeping the excitation power below Pth at room temperature. Here, we demonstrate the switching on of the PA-like mechanism by an auxiliary beam at 808 nm, which is in resonance with the Nd^{3+} ground-state transition $^4I_{9/2} \rightarrow \{^4F_{5/2}, ^2H_{9/2}\}$. It comprises the first, to the best of our knowledge, demonstration ofan optical switched PA, and the underlying physical mechanism is the additional heating ofthe particles due to the phonon emissions from the Nd^{3+} relaxation pathways when excitingat 808 nm. The present results have potential applications in controlled heating and remote temperature sensing.

Optimization of Graphene Oxide Synthesis: influence of the graphite-oxidant ratio on the BET surface area

Bruna de Paula Chaves[1], Jéssica Menezes de Mélo Luzardo[1], Karoline Charles Martins[1], Joyce Rodrigues Araujo[1]

[1]Instituto Nacional de Metrologia, Qualidade e Tecnologia (*Divisão de Metrologia de Materiais*)

e-mail: brunapchaves@outlook.com

Graphene is a nanomaterial composed of carbon atoms forming a hexagonal structure. It is well known that their crystals are the thinnest one and have great commercial interest due to their electrical and mechanical properties. Among the existing synthesis methods, the most used are through chemical routes[1]. The chosen method for this work was the Hummers method[1]because it has several advantages in terms of process efficiency and reproducibility. In the Hummers methodology, graphene oxide (GO) is obtained through an oxidation reaction of graphite, where several π bonds react to incorporate functional groups such as carboxyl, hydroxyls and carbonyls, depending on the intensity of the oxidation reaction, making GO rich in sp^3carbon[2]. The aim of this study was to compare graphene oxides produced using different graphite-oxidant ratios and correlate the material oxidation with its BET surface area. Through characterization by some techniques, it was noticed that the larger the graphite-oxidant ratio, more intense the change in its structure, that is, as higher the proportion between them, more successful the oxidation process[3]. This directly implied on the increase on the BET surface area of the material: increasing the graphite-oxidant proportion from 1:3 to 1:6, one order of magnitude increase in the BET area was observed. Following this logic, it was possible to modify pre-existing methods in the literature in order to find an ideal proportion to reach larger surface areas.

Optoelectronic properties of MoS_2 devices for hybrid solar cells applications

Allan Tardiolle[1], Ney Pereira Mattoso Filho[1], Alex Aparecido Ferreira[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: tardiolleallan526@gmail.com

Two-dimensional metal dichacogenides have been under intensive research due to the potential applications in optoelectronics devices. Thin film semiconductors, such as Molybdenun disulfide (MoS_2), are a promising alternative semiconductor for hybrid photovoltaic technologies due to its absorption in the near-infrared spectrum, its good charge carrier transport and its ability to easily form 2D structures. In this work we focus on the investigation of optical properties of MoS_2dilluted in ethanol. We have studied the broadband response to ultraviolet, visible and near-infrared (UV-Vis-NIR) range. Our results will be used in the development hybrid solar cells using MoS_2.

e-mail: abarboza@iprj.uerj.br

Silicene is a promising material due to its potential to have unique electronic, optical and mechanical properties that could be useful in various technological applications. These properties, however, depend on the honeycomb structure of silicene, which has already been shown to have several stability issues. Its monolayer form is only stable when attached to a substrate, which may hinder its application capability. Conversely, its bilayer structure can theoretically be stable in free-standing form, especially when doped. The existing works are still in their early stages and do not consider more realistic structures, such as polycrystalline silicene, which will certainly occur with large-scale synthesis. In this context, this work investigates the stability and mechanical properties of polycrystalline bilayer silicene doped with aluminum. To this end, we applied molecular dynamics simulations using a recently develop ADP potential for Si-Al available in the literature [1]. Polycrystalline bilayer silicenes with AA stacking were created using the Voronoi tessellation with a size of 270 Å x 270 Å containing different percentage of Al, ranging from1 to 4%. The results show that the systems remains stable even at room temperature, withAl atoms deviating from the silicene sheet by 0.7 Å, causing a von Mises shear strain of 0.16in the nearby lattice. However, the doping level does not significantly impact the silicenestrength compared to a non-doped polycrystalline silicene, as the deformation and, consequently, the fracture occurs at the grain boundaries. These results suggest that polycrystalline bilayer Al-doped silicene can be a candidate for electronics applicationswhere some strain levels are required at room temperature.

Ramam Spectroscopy Studies of $PtSe_2$ and The Formation of Selenium Vacancies Using Temperature

Carolina Pirogini Torres[1], Daniel Angeli de Moraes[1], Iara de Lacerda Pataca[1], João Batista Souza Junior[1], Edson Roberto Leite[2]

[1]Brazilian Center for Research in Energy and Materials (*LNNano*) , [2]Brazilian Center for Research in Energy and Materials

e-mail: carolinapirogini@gmail.com

Platinum diselenide ($PtSe_2$) is a Transition Metal Dichalcogenides (TMD) material with potential for applications on hydrogen evolution, optoelectronic devices, and photocatalytic applications. TMD materials have weak van der Waals interaction between interlayers, which creates a passaway to exfoliate those materials and separate into two-dimensional (2D) nanosheets. Raman spectroscopy is an essential characterization tool for 2D materials with potential to understand defects due to the sensitivity of Raman technique with the breaking of the conservation of momentum rule, i.e. Raman peaks can shift, broaden, change their relative intensity, or additional peaks occur with the presence of defects. The main defects studied for Raman are vacancies, isolated functional groups, substitutional atoms, dislocation, and grain boundaries. In this work, a thin film of PtSe2 was obtained through the selenization of a metallic platinum substrate and Ramam spectroscopy was used to study its structure and stability over a range of temperatures (RT-500°C). Transmission Electron Microscopy (TEM), X-ray Diffraction (XRD), Scanning Transmission Electron Microscopy (STEM), and X -ray Photoelectron Spectroscopy (XPS) characterizations were performed before and after the in-situ Raman temperature studies. It was possible to observe the effects of temperature and the generation of defects of selenium vacancies on the material with the Raman peaks shift to lower energy possibly due to the local atomic change in the structure and the appear of LA band (Longitudinal Acoustic Mode), considered a defect band in Raman Spectroscopy.

Reduction of MoO3 with organic acids activated by microwave radiation

Joana D'ark Santos Barbosa[1], Aldebarã Fausto Ferreira[1], Walter Mendes de Azevedo[1]

[1]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*)

e-mail: darksantos190@gmail.com

Reduced molybdenum oxide (MoO_{3-x}) is an important 2D material with a wide range of applications as catalysis, analytical chemistry and sensors. Its obtention have been made by several methods like solvothermal, hydrothermal and microwave exfoliation [1,2]. Furthermore, it is known that water dispersed nanosheets of MoO3 can be easily reduced by ascorbic acid [1]. Although, bulk molybdenum oxide does not react in that same way. The aim of this work was demonstrated that microwave potentialize the MoO3 reduction by ascorbic acid and activate it reduction by organic acids which presents -COHCOOH structure. For this purpose, bulk and exfoliated MoO3 was placed to react in a water solution of ascorbic acid through 30 min under microwave radiation at 120 °C. Moreover, reaction with organic acids (acetic, succinic, citric, lactic, malic or tartaric acid) were conducted, 1:1 and 2:1 molar ratio of organic acid to molybdenum oxide were evaluated. UV-Vis measurements presents absorption bands centered at 690, 800 and 1000 nm related to Mo6+ reduction to Mo5+ and Mo4+ [3] when reacts with ascorbic acid, lactic acid, malic acid or tartaric acid. Further, the samples were characterized by SEM, FTIR, Raman and XRD. A new mechanism based on molecule polarization by microwave radiation was proposed to explain those results. Steric effect supports the unreactive of MoO3 with citricacid.

Monolayer transition-metal dichalcogenides (TMDs), with unique electronic and optical attributes not found in their bulk forms, have recently attracted significant attention from the scientific community [1]. In particular, due to their non-centrosymmetric nature and relatively large second-order nonlinear susceptibility, these materials can exhibit an unusual nonlinear optical response [2]. However, the atomic thickness of these monolayers limits the interaction between the TMDs and light, generally resulting in an inefficient second-harmonic generation (SHG) process [3]. Here, we demonstrate SHG enhancement of MoS_2monolayer via surface plasmons generated at square gold gratings composed of 20 μm long sub-wavelength slits with a width of 100 nm and separated by distances varying from 1000 nm to 300 nm. The SHG signal from the hybrid device is three times greater than the signal from MoS_2deposited on flat gold and does not show peak broadening in the spectra. Additionally, the dependence of SHG intensity on excitation power showed two distinct regimes. A slope of ~ 1.9 was observed for low excitation powers, revealing a quasi-quadratic dependence consistent with the second-order nonlinear process. For high excitation powers, the slope is reduced to less than one, indicating saturation of the SHG process. Our work sheds light on the physical mechanisms of SHG in MoS_2-plasmonic nanostructures and may help the development of efficient integrated nonlinear devices.

Strain engineering of MoS2 monolayers onto highly stretchable electrodes for electrochemical hydrogen production

Leonardo Hideki Hasimoto[1,2], Murilo Santhiago[1,2]

[1]Universidade Federal do ABC (*Center for Natural and Human Sciences*) , [2]Brazilian Center for Research in Energy and Materials (*Brazilian Nanotechnology National Laboratory*)

e-mail: leonardo.hasimoto@lnnano.cnpem.br

Molybdenum disulfide has been considered a promising material for application as an electrocatalyst for hydrogen evolution. However, in its natural form, it has poor activity, requiring defect engineering steps through methods such as chemical etching and thermal annealing[1] to activate its basal plane. Associated with the creation of defects it was demonstrated that by applying mechanical strain to MoS2 layers it is possible to further increase its performance due to the modulation of its band energies. Typically, most of the works studying the influence of strain on MoS2 activity employ rigid substrates containing microcone structures of fixed sizes and diameters, limiting the deformation to a certain value. On the other hand, using an elastomeric substrate for the fabrication of modified electrodes makes it possible to tune the strain at different levels in the same device, in addition studies of deformation cycles can be carried out. With these considerations, this work presents initial results related to the development of a polydimethylsiloxane-based stretchable electrode for later application in the development of functional electrodes based on MoS2. After the fabrication of the electrode, bulk MoS2 is transferred onto the electrode's surface and electrochemically thinned in 0.5 M H_2SO_4 solution in a second step[2]. The ultra-large MoS2 monolayers were characterized by Raman and photoluminescence. Chemical etching using H_2O_2 and the formation of the corrugated surface will be shown.

The objective of this work is to study the morphological and electric properties of the composite made from the mixture of MoS2 and PEDOT:PSS in different proportions, using water as a solvent. PEDOT:PSS is a polymeric material made from two different polymers, poli(3,4-etilenodioxitiofeno) (PEDOT) and polystyrene sulfide (PSS), due to its high conductivity is commonly used in electrical devices such as organic photovoltaics (OPVs), sensory gases and organic thermoelectric (TE) [1], [2]. MoS2 is a semiconductor that can be exfoliated in a bidimensional material, highly used in the industry as a lubricant due to its weak interaction between its layers (Vander Walls force). Due to its electric properties, 2D-MoS2 is being used in other applications, for example, used as an electrode in a solar cell [3]. The mixtures were made using the 2D-MoS2 as a base and then doing the percentage of PEDOT:PSS, varying the sample from 10% to 45%. To do the morphology analyses we obtain images from Scanning Electron Microscope (SEM), Transmission Electron Microscopy (TEM) and Atomic Force Microscopy (AFM). The electric characterization was made from the 4 probe method, which showed us a significant improvement in the electric properties up to 2 orders of magnitude if compared to the pure PEDOT:PSS. Acknowledgments: This work was supported by CNPq, CAPES, PIPE - UFPR,UFMG.

Graphene, an exceptional nanomaterial, has garnered significant attention due to its extraordinary properties and potential applications. This ongoing study aims to conduct a comparative analysis of reduced graphene oxide (rGO) synthesized via the modified Hummers'' method from graphite and via thermochemical reduction from sawdust, for incorporation into a polyvinyl chloride (PVC) matrix. The synthesized rGO samples will undergo characterization using Raman spectroscopy, with the aim of identifying G and D peaks that have values of width at mid-height greater than 30cm^{-1}. This will confirm the presence of functionalized graphene or graphene oxide. In addition, scanning electron microscopy (SEM) will be utilized to analyze the lateral thickness of the flakes, which contributes to determining the amount of stacked graphene layers present in the synthesized sample. The thickness of ~0.34nm corresponds to a single graphene layer. A comparison of the rGO samples will be conducted to demonstrate the feasibility of using sawdust as a sustainable alternative precursor for graphene synthesis, with the aim of reducing the amount of this waste product. In Brazil, it is estimated that 30 million tons of sawdust are generated each year [1]. Subsequently, the synthesized rGO will be incorporated into a PVC matrix [2]. The resulting nanocomposites will undergo characterization for their mechanical and thermal properties, using tensile testing and TGA, to confirm the possible application of rGO synthesized from wood sawdust.

Gas sensing devices based on two-dimensional (2D) materials have excellent gas detection performance. The two-dimensional structure of 2D MoO_3:graphene nanocomposites has been studied for this purpose, as it has a large specific surface area, which increases the adsorption capacity of the gas [1]. The graphene layer acts as a conductive platform that facilitates the transfer of electrons from the $MoO_3$to the gas molecules, leading to a change in the electrical properties of the device [2]. The high sensitivity, selectivity and stability of 2D-MoO_3:Graphene gas sensing devices make them promising candidates for practical gas detection applications. This work describes the characterization of the two-dimensional composite and its application in the active layer of an alcohol gas sensor device. The tests were carried out in ambient atmosphere, under variation of alcohol gas concentration (ppm) and temperature (20 - 120 ºC), with the objective of verifying the response to resistance variation, that is, gas detection in different scenarios.

Metal-organic frameworks (MOFs) are porous structures built from the coordinative bond between metal ions and organic ligands. One of the unique characteristics of MOFs is their permanent porosity. Modifications to its geometry, length, aspect ratio, and functional groups can adjust the , shape, and inner surface properties of a MOF for a variety of applications. However, certain interferents, such as limited thermal and mechanical stability, led scholars to associate MOFs with carbon-based materials, such as graphene oxide and reduced graphene oxide [1]. Thus, this study aimed at the synthesis and characterization of MOF@GO and MOF@rGO nanocomposites. Therefore, the graphene derivatives, GO through the modified Hummers method, and the rGO from the chemical reduction using Ascorbic Acid (L-AA) were obtained. The MIL-100(Fe)@GO and MIL-100(Fe)@rGO nanocomposites were obtained using the solvothermal method. The synthed materials were characterized by X-Ray Diffraction (XRD), Infrared Absorption Spectroscopy (FTIR), Scanning Electron Microscopy (SEM), Thermogravimetric Analysis (TGA) and Raman spectroscopy. The Raman spectra confirmed the obtaining of GO and rGO, which had their average number of layers estimated from the broadening of the diffraction peaks referring to the basal plane and the Scherrer equation. XRD data also confirmed the crystallization of MOFs in the composites. The SEM images of the nanocomposites suggest the formation of MOF crystals randomly anchored and dispersed on the surface of GO and rGO. Thermogravimetry data indicate that both nanocomposites have three mass loss events, however the MIL-100(Fe)@rGO system was more stable.

This work aims to study graphene synthesis via Chemical Vapor Deposition - CVD, without the use of metallic catalysts. We were able to grow the films directly on a SiO2/Si substrate (300 nm oxide thickness). We demonstrate that the growth of graphene without catalysts is not self-limiting, that is, the film thickness is strongly dependent on the growth time. We investigated different deposition times and observed differences in film thickness and covered area. With longer synthesis time, we observed that the films tend to be less crystalline, despite the better coverage. In order to obtain more crystalline films with fully covered substrates, we developed a CVD growth method called "pulsed gas CVD growth". This method is innovative, as we are not aware of other works in the literature with its application. The pulsed gas flow consists of a growth with curing times throughout the deposition, when the insertion of the carbon precursor (CH4) is interrupted for interspersed periods during the growth. The characterization of our films was performed by scanning electron microscopy (SEM), Raman spectroscopy and electrical characterization by Hall Effect. We observed that the material we synthed is p-type doped, which is in agreement with other works in the literature [1]. This fact is probably related to the CO and CO2 impurities present in the sample. To exemplify in practice the interest of this type of synthesis, we built a field effect transistor using samples grown with continuous and pulsed gas flows. We observed the variation of the Fermi level, the increase of the current and the conductivity of the synthed materials.

e-mail: rodrigo.perito@labmat.ufsc.br

Coatings are regularly used for decorative purposes and for surface protection. The coatings industry, like many other, is constantly researching and developing new technologies for the formulation and application of new and better coatings. Since 2004, when the graphene (GO) nanomaterial was first isolated, scientists in the coatings industry have been looking for ways to use GO as an additive to improve the performance and technology of coatings in different application areas. GO enables a wide array of functional coatings, for many possible applications. GO is a single, tightly packed layer of carbon atoms arranged in a hexagonal honeycomb lattice. It is the thinnest compound known to man at one atom thick, the lightest material known, the strongest compound discovered. Incorporating GO into a decorative paint can increase its chemical and mechanical resistance and offer greater surface protection. Therefore, different percentages of GO (1.0; 1.5 and 2.5 %) were added in the formulation of a styrene acrylic decorative paint with an eggshell finish. The addition of GO was performed by milling the concentrate with zirconium spheres for 40 min followed by adding the other raw materials by mechanical dispersion using a Cowles-type disc for 20 min. The properties of the standard paint and with different percentages of GO were measured through Konig hardness (ABNT NBR 14946), washability (ABNT NBR 15494), contact angle and surface energy (ramé-Hart 250 goniometer), rheology (Haake ViscotesteriQ, Thermo Fischer Scientific Inc.), and staining tests (coffee, ketchup, oil and wine). The obtained results were promising, with gains in properties, increasing the hardness and washability resistance of the coating, hydrophobic characteristics, as well as improving resistance to staining.

Acknowledgements: The authors would like to acknowledge Anjo Tintas for the financial support, for supplying the paint base and for making the R D laboratory available to carry out the tests.

Theoretical investigation of Graphenylene Nanoflakes stacking effects on optical and electronic properties

Gabriel Henrique Batista[1], RICARDO BRANDOLT JÚNIOR[2], Ricardo Paupitz[3] [1]Universidade Estadual Paulista (*Física*) , [2]Universidade Estadual Paulista (*IGCE - Física*) , [3]Universidade Estadual Paulista

e-mail: gabriel.batista@unesp.br

In the last decades, the study of two-dimensional materials has sparked great interest in the scientific community. Graphene, synthed in 2004, has paved the way for advancements in nanoscience and nanotechnology. One of the promising materials in this field is graphenylene, a two-dimensional porous carbon-based material with a structure analogous to graphene and interesting electronic and optical properties. In this context, computational simulations have been instrumental in investigating the properties of these materials at the nanoscale. In this work, the DFTB approximation was used to simulate the stacking of passivated graphenylene nanoflakes. We analyzed different s and shapes of flakes, investigating their optical and electronic properties. Our simulations indicate that stacking of graphenylene nanoflakes can modify optical and electronic properties such as absorption, electronic gaps and the frontier orbitals. Notably, the intensity of absorption peaks decreases as flakes of the same type are stacked. This behavior suggests an interaction between the flakes in the stacking, thereby influencing light absorption and electronic behavior in comparison to monolayer nanoflake. This study can contribute to the advancement of knowledge about the behavior and properties of stacked graphenylene nanoflakes. The performed computational simulations provide valuable insights into the relationship between the stacking structure and the optical and electronic characteristics of these systems. Therefore, the obtained results can be useful in the development of future applications.

Low-dimensional carbon-based materials have been the subject of several studies in the last two decades due to their physical properties[1]. In particular, graphene has been widely used in various fields, and it can be synthed by many methods, such as chemical vapor deposition (CVD), which is an efficient method to obtain large-scale and high-quality graphene. A lot of studies have been made regarding CVD growth using metal foils as catalysts. However, for device applications, we have to transfer the as-grown graphene onto another suitable substrate from the metal catalyst surface which needs a series of processes that sometimes may compromise sample quality. Recently, some work has been done towards the direct growth of graphene by CVD on desired target substrates [2,3]. The posterior growth of other materials on top of graphene, such as transition metal dichalcogenides (TMDs), can provide heterostructures that could be interesting in nanoelectronics. In this work, we propose to obtain TMDs or HS grown directly on a sp2 carbon film, all structures grown by CVD method on top of a Si/SiO2 substrate, avoiding any transfer process. We perform spectroscopic measurements to compare these samples with transfer-based carbon-TMD HS in order to infer the differences in layer interaction for both structures.

Trimetallic layered double hydroxides with the composition $[Zn^{2+}_{6-x}M^{2+}_{x}Al_{3}(OH)_{18}][(SO_{4})_{2}Na]\cdot yH_{2}O$ (M^{2+}= Co, Mn).

[1]Universidade Federal do Paraná (*Química*)

e-mail: vv.machado@ufpr.br

Synthetic layered double hydroxides (LDHs) with the ideal composition [M2+6Al3(OH)18][(SO4)2Na]·12H2O were recently described [1,2]. To expand this class of compounds, trimetallic LDHs with composition [Zn6-xM2+xAl3(OH)18][(SO4)2Na].yH2O (M2+=Co, Mn) (x=0 to 6) were synthesized. Solutions of the metal sulfates of M2+, M3+ and Na2SO4 (molar ratios of 6:3:1), with different proportions between Co2+ and Zn2+, were titrated with a 1 mol L-1 NaOH solution until a pH = 9-9.5. The materials in the presence of the mother solution were treated at 90 °C for 120 h, centrifuged at 4500 rpm, washed several times with water after redispersion, and dried at 50 °C for 72 h. X ray diffraction indicated crystalline phases with basal spacing close to 11 Å, attributed to the intercalation of SO42- in a double layer arrangement in the presence of hydrated Na+. A reduction in the basal distance was observed when Zn is replaced by Mn or Co, according to the reduction of the ionic radius. The ICP-OES analyzes confirmed the expected compositions and FTIR analyses showed bands attributed to the O-H and M-O bond, S-O bands of sulfate, in addition to a linear shifting of the M-O band due to the replacement of Zn by Co or Mn, according with Vegard's law [3], which states that a linear correlation should be observed when metals with different ionic radii are used in a solid solution. This new trimetallic LDHs, which can exchange cations, anions and even both simultaneously, present potential applications in different areas of science and technology.

Two-dimensional oxide structures of perovskitestructure via sacrificial layer dissolution

Gilson Lopes[1], Marcia Tsuyama Escote[1]

[1]Universidade Federal do ABC

e-mail: gilson.lopes@ufabc.edu.br

Recently, Two-dimensional oxides and their application in flexible and wearable electronics films have been extensively studied, due to their potential applications in sensors, biomedical and electronic devices. So, there is an effort to development of different synthesis routes to obtain freestanding inorganic films, which can be manipulated and used to build new functional electronic devices, aiming to reach a synergy between the greater degree of mechanical freedom and the amplification of the performance of well-known functional oxides. In this work, we report the fabrication of freestanding RNiO3 (R= La and Nd) thin films using NaCl and Sr3Al2O6 (SAO) as sacrificial layers. The NaCl layer were grown using thermal deposition method and the SAO were deposited through a chemical solution deposition (CSD) method, both films were grown on SiO2/Si(100) substrates. Over these sacrificial layers were deposited 1 to 3 layers of an R-Ni precursor solution and each layer were heat-treated at 700 °C in oxygen atmosphere to obtain RNiO3 heterostructures. The structural and microstructural characteristics of these films were evaluated by X-ray diffraction, Raman spectroscopy and scanning electron microscopy. The X-ray results revealed the formation of the NaCl phase, whereas the SAO phase was only reached at a temperature of 1000°C. An initial analysis suggested that de NdNiO3/SAO/SiO2/Si(100) film crystallized in the desired phase. Although, preliminary solubility tests showed that de SAO films were not water-soluble, they seem to be slightly soluble in basic solution. The NaCl films present high solubility in water. The NdNiO3/NaCl/SiO2/Si(100) films present a rough surface, but it seems to present a homogeneous and crack-free film. The electrical resistance as a function of temperature is going to be evaluated of the film over the sacrificial layers and freestanding.

Water Structure and Dynamics inside Two-Dimensional MoS2

Gabriel Fidencio Murillo[1], MATEUS HENRIQUE KÖHLER[2]

[1]Universidade Federal de Santa Maria (*Departamento de Química*) , [2]Universidade Federal de Santa Maria (*Departamento de Física*)

e-mail: gabriel.murillo@acad.ufsm.br

Computational studies on confined water have advanced the field of materials science and nanofluidics in the last decades. They provide a detailed understanding of the water properties and how it is influenced by the geometry and nature of the confining materials. Particularly, MoS2 nanochannels have been proposed as a prominent water sieve, with high selectivity and water flow. Two-dimensional MoS2, with a combination of hydrophobic and hydrophilic sites were shown to even exceed the water flow rate found in pristine graphene. This highlights the importance of studying these materials. Here, we propose a Molecular Dynamics (MD) study of water confined between monolayers composed of MoS2 and graphene oxide using the LAMMPS software. The results show a water organization in layers depending on the distance between the solid-state plates. The structuration also depends on the material and the level of oxidation of the graphene. The results highlight how nanoconfined water behaves differently from bulk and the possibilities for its application.

Magnetic properties at high H/T regimes

Fernando Luis de Araujo Machado[1]

[1]Universidade Federal de Pernambuco (*Departamento de Física*)

e-mail: fernando.machado@ufpe.br

Magnetic materials under high applied magnetic fields and at low temperatures present unusual electronics, thermal and magnetic properties that are governed by the H/T ratio. The generation of magnetic fields above the limits imposed by commercial superconducting solenoids is not a simple task, demanding for complex infrastructures and substantial financial support. Fortunately, there are few laboratories, like the National High Magnetic Field at Tallahassee -NHMFL, that are open for the magnetism communities worldwide allowing the access to large H/T regimes. In this presentation, I will review some former experimental results [1-4] I was involved with as well as to discuss some experiments that are underway.

Acknowledgments: Many thanks to my collaborators along the years and to the NHMFL for providing full support to our research work. Financial support from FINEP, CNPq, CAPES and FACEPE are also acknowledged.

Stabilizing skyrmions on ordered arrays of nanodomes and nanodisks.

Juliano Casagrande Denardin[1]

[1]Universidad de Santiago de Chile (*Física*)

e-mail: jcdenardin@gmail.com

Magnetic skyrmions are non-trivial spin textures that resist external disturbances and are promising candidates for the next generation of magnetic recording devices. However, a major challenge in the realization of devices based on skyrmions is the stabilization of ordered arrangements of these spin textures under ambient temperature and zero applied field conditions. In this work we study the formation and stabilization of magnetic skyrmions in Pt/Co/Ta multilayers. We also demonstrate for the first time the formation and stabilization of magnetic skyrmions on arrays of self-assembled hexagonal nanodomes [1]. Magnetic force microscopy (MFM) images of the arrays of nanodomes with 100 nm shows isolated skyrmions at remanence, as the special topography helps to stabilize the skyrmions in the hexagonal arrangement of the nanodomes. We also investigate the effect of constriction on the nucleation behavior of skyrmions in nanodisks with different diameters, fabricated by electron beam lithography. These systems have been characterized by MFM by MOKE, and micromagnetic simulations were compared with experiments to determine the correlation of the domain textures with the topography of the samples and with the applied field and magnetic parameters of the multilayers.

Tailoring ultrathin film growth for integration in high performing magnetic sensors

Suzana Cardoso[1], Felipe Bohn[2]

[1]INESC MN, [2]Universidade Federal do Rio Grande do Norte (*Departamento de Física*)

e-mail: scardoso@inesc-mn.pt

Nanoelectronics combines physical principles of materials with the impressing capability of engineering ultra-small devices at the nanoscale. Magnetic field sensors, in particular, magnetoresistive MR sensors, were driven by the technological push from computers and information storage in the early 1990's. Presently they have a mature and transversal levelof implementation in the market, from automotive to biomedical domains. In this talk, I willfirst introduce key concepts in spintronics and highlight the physics mechanisms defining the sensor performance and the figures of merit for the classification of an outstanding MRsensor.
The materials discussed include several varieties of thin films: oxide films as tunneling barriers, ultrathin amorphous and crystalline films, ultrathin textured layers with grain size control, magnetically soft layers or antiferromagnetic films - all combined onto multilayer stacks, typically thinner than 60nm. In addition, the noise mechanisms (the "killing factor" that limits the MR sensor performance) will be discussed, and I will showsuccessful strategies for improving the signal-to-noise ratio, improving the ultimate field detectable by an MR sensor.

The detection principles, sensor design, simulations and experimental validation will be discussed for exciting applications where MR sensors bring added value over other competing technologies. Further, I will show how challenging applications have identified creative solutions, requiring joint skills in transversal areas as physics, materials, electronics and mechanical engineering. I expect academics and engineers to be encouraged to propagate their expertise in magnetism to the young, talented people we see every day, so to trigger innovation in future spintronic sensors.

Assessing the relaxation mechanisms contributions through the magnetoimpedance effect in YIG/W bilayers

João Gustavo da Silva Santos[1,2], Edimilson Felix da Silva[3], Matheus Gamino Gomes[3], Felipe Bohn[4], Marcio Assolin Correa[4]

[1]Universidade Federal de Pernambuco (*Física*) , [2]Universidade Federal do Rio Grande do Norte (*Física Teórica e Experimental*) , [3]Universidade Federal do Rio Grande do Norte, [4]Universidade Federal do Rio Grande do Norte (*Departamento de Física*)

e-mail: joao.gutavo@gmail.com

To study the effect of spin pumping (SP) through the variation of the thickness of the ferromagnetic material (FM) it is important to take into account the two magnon scattering process (TMS). These two effects are known as magnetic relaxation mechanisms and can be estimated through the damping parameter that carries information from intrinsic and extrinsic relaxation mechanisms. One way to evaluate these mechanisms is to analyze, through ferromagnetic resonance (FMR), the line width (ΔH) and consequently the effective damping parameter (α_{eff}). This type of analysis can be done through a traditional FMR experiment, where a fixed frequency is associated with the resonant cavity, or through more sophisticated experiments. For example, using a vector network analyzer (VNA) that allows investigation not only by varying the angle and amplitude of the magnetic field, but also by sweeping the probe frequency. As an alternative to overcome disadvantages in the context of technological applications, we adopted the magnetoimpedance (MI) technique to evaluate ΔH and α_{eff}. However, this choice brought the challenge of performing an electrical measurement on an insulating material, in this case yttrium iron garnet ($Y_3Fe_5O_{12}$- YIG). This material is a ferrimagnetic insulator that has a low damping parameter that makes it a promising candidate for exploring magnetization dynamics. In this work, we evaluate the role of TMS and SP in magnetization relaxation by estimating α_{eff}through the MI effect in YIG/W bilayers, where W is tungsten. By modifying the thickness of the YIG, we explored the contributions of such extrinsic mechanisms to $\alpha_{eff}$and their contributions to the MI response. Our results reveal that the sample geometry allows us to manipulate the magnetoimpedance response over a wide range of frequencies and magnetic fields by mapping the contribution of SP and TMS to the effective damping parameter.

Correlation between interfacial atomic intermixing and the formation of skyrmions

Pamela Costa Carvalho[1], Ivan de Paula Miranda[2], Jeovani Brandão[3], Anders Bergman[2], Julio Criginski Cezar[3], Angela Burlamaqui Klautau[4], Helena Maria Petrilli[1]

e-mail: pamela.costa.carvalho@usp.br

Among the novel two-dimensional topological magnetic structures investigated in the literature, skyrmions are nanostructures which have large application in the design of new technologies, specially storage devices. One of the main interactions known to be responsible for its stabilization is the Dzyaloshinskii-Moriya interaction (DMI), which arises in the presence of broken inversion symmetry and its strength is related to a large spin-orbit coupling (SOC). Although, asymmetric interfaces which combine magnetic and heavy elements are of great interest in the search for skyrmions, recent experimental works put symmetrical interfaces in perspective as candidates to host topological nanostructures with the observation of room temperature skyrmions in Pd/Co/Pd multilayers. A possible origin for a non-null DMI in these symmetrical stackings is the existence of interfacial interdiffusion, where intermixing of atoms might occur during the deposition process, specially in thin films grown by magnetron sputtering. In this work, using real-space first-principles calculations [6] together with atomistic spin dynamics [7], we investigate the Pd/Co/Pd multilayers, focusing on correlating interfacial atomic intermixing and the formation of skyrmionic phases. Here, through ab initio calculations, we show that the DMI strength is strongly enhanced by the presence of defects, due to a local symmetry breaking induced in the system. Besides that, through atomistic spin dynamics simulations we explore the different magnetic phases and the effects of PMA through a phase diagram and our results indicate that a larger DMI, compared to the pristine case (without defects) can stabilize metastable skyrmions in Pd/Co/Pd multilayers.

In the early days of microelectronics, electromigration was a significant source of failure in circuits. However, it has been shown that, by fine-tuning the threshold current density that triggers this phenomenon, one can modify - in a controllable manner - the material properties at an atomic scale. In this work [1], we investigate the localized material modifications produced by electropulsing on Al capped Nb microbridges with multiterminal configuration. The affected regions on the Nb/Al bilayer terminals are revealed by an in-lens secondary electrons detector in a scanning electron microscope as well as by Kelvin-probe force microscopy, both suggesting a decrease of the work function in the modified areas. In contrast to that, the affected areas are neither apparent through an Everhart-Thornley secondary electrons detector nor through atomic force microscopy, which indicates little morphological changes on the microstructure. These results are elucidated by complementary finite element modelling which permits us to estimate a threshold temperature of (435 ± 35) K needed to induce material modifications. In addition, we demonstrate that the extension of the electroannealed regions is strongly influenced by the terminal geometry, resulting in weak links which affect the superconducting transition. These findings provide further insights on the subtle modifications produced by gentle electroannealing of Nb/Al microstructures and represent a step forward towards mastering this emerging nanofabrication technique.

Effects of Local Spin-Density Waves in Antiferromagnetic phases in Cr-V Alloys

Letícia Maria de Oliveira[1], Paulo Eduardo Narcizo de Souza[2], Paulo Cesar de Camargo[3], Adilson J A de Oliveira[4]

[1]Fundação Universidade Federal do Vale do São Francisco (*Colegiado de Ciências da Natureza*) , [2]Universidade de Brasília (*Nucleus of Applied Physics*) , [3]Federal University of SaoCarlos (*Physics Department*) , [4]Federal University of Sao Carlos (*Física*)

e-mail: leticia.maria@univasf.edu.br

The magnetic behavior of Cr and its alloys still poses questions related to the itinerant magnetism described by spin-density waves (SDW) [1]. The introduction of small amounts of V in Cr (up to 0.4 at%V) leads to the formation of localized magnetic moments. In the paramagnetic phase, a Curie-Weiss behavior is observed for magnetic fields up to 10 kOe [2,3] giving an evidence of local magnetic moments. The origin of localized magnetic moments in Cr-V alloys can be explain based on the formation of local SDW. A rearrangement of SDW resulting on a short range order, around impurities and different kind of defects, were shown to lead to a self-redistribution of the charge and spin densities in their vicinities [4]. In this present work we reported the observation of magnetic irreversibility associated with local SDW in Cr 0.4 at.%V. The DC magnetic susceptibility measurements were measured using a SQUID magnetometer MPMS-5S from Quantum Design. The temperature dependence of magnetization (M) was measured in the range 5 · T □ 400 K, with increasing temperature, after cooling in zero magnetic field (H) (ZFC), and follow by decreasing temperature, under field cooling (FC), at the same applied magnetic field. The results show irreversibility between the FC and ZFC curves that decreases under applied magnetic field. This behavior is associated to the local SDW due to a magnetic anisotropy directly affecting the long-range order of SDW.

Fabrication and measurement of superconductingqubits

In recent years, the development of techniques to observe non-classical behavior in nano-scale mechanical structures has brought significant attention due to their potential for fundamental studies of quantum mechanics and new applications such as sensing weak forces and quantum communication [1]. One important approach is through the coupling of nanomechanical resonators with superconducting qubits, which recent experiments have started to develop as tools to manipulate and measure quantum states of mechanics [2]. We are interested in transmon-type superconducting qubits for read-out and control of nanomechanical resonators. This talk will cover preliminary system designs and our efforts to develop transmon qubits coupled to microwave cavities.

Ground-state phase diagram and universality of topological valence-bond-solid quantum phase transitions in a ferrimagnetic Heisenberg tetramerchain

Marcelo Leite Lyra[1], Luan Felipe Santos Martins Veríssimo[1], Maria Socorro Seixas Pereira[1]

[1]Universidade Federal de Alagoas (*Instituto de Física*)

e-mail: marcelo@fis.ufal.br

The ground-state ordering of a quantum mixed-spin Heisenberg tetramer chain composed of an alternate sequence of s=1 and S=3/2 dimers is studied in detail as a function of two considered exchange interactions ascribed to similar and dissimilar spin pairs. At zero magnetic field, the ferrimagnetic mixed spin-(1, 1, 3/2, 3/2) Heisenberg tetramer chain displays, depending on a mutual interplay between two considered exchange interactions, three distinct gapped valence-bond-solid phases separated by gap-closing quantum critical points. Using density-matrix renormalization group calculations we construct the full ground-state phase diagram as a function of the interaction ratio and magnetic field, which exhibits besides three gapped valence-bond-solid phases special Kosterlitz-Thouless and topological quantum critical points. A tangential finite-size scaling analysis is employed to obtain precise estimates of the zero-field valence-bond-solid transitions and unveil their common logarithmic correction to a power-law scaling of the correlation length.

Magnetic domains stabilization on curved substrate

Magnetic domains and skyrmions have an excellent potential for application in new-generation spintronic devices. For instance, hexagonal arrays of skyrmions are good candidates for media recording [1]. It is demonstrated by the theory/simulations that bent surface topologies are suitable to stabilize the different magnetic textures, such as magnetic domain and skyrmion; moreover, vortex [2,3]. In this work investigated the magnetic domains in a self-supported micro-membrane using a self-organized array of polystyrene spheres (PS) templates. By colloidal lithography, we fabricated an array of polystyrene spheres to obtain a curved substrate and explore its effect. We produced substrates with different sphere diameters, which allow exploring the impact of curved nanocaps over the magnetic texture. Co/Pt and NiFe thin films (by magnetron sputtering) were grown over the PS arrays. The stacking, mainly the Co and NiFe layer thickness, was varied to obtain different magnetic properties. These systems allow us to explore magnetic texture in the function of the curvature and magnetic properties. By dissolution, we remove the polystyrene sphere to produce self-supported membranes with an "egg box" conformation. The structure and size of the membrane were investigated by scanning electron microscopyand transmission electron microscopy. We observed that all samples form self-supported membranes with a well-organized array of nanocaps. We investigated the magnetic domain on these membranes by magnetic force microscopy and electron holography. Tuning the curvature effect and magnetic properties of nanocaps, we obtained the hexagonal array of monodomain, stripes, vortex, or skyrmions. Our results show that it is possible to stabilize the different magnetic domains on self-supported nanocaps, which can be used for high-density recording information.

Magnetic flux distribution in superconducting films decorated with an array of pinning centers: influence of the geometry of antidots

Wilson Aires Ortiz[1]

[1]Departamento de Física, Universidade Federal de São Carlos

e-mail: wortiz@df.ufscar.br

Considering a noncentrosymmetric pinning texture composed of a square array of triangular holes, the magnetic flux penetration and expulsion are investigated experimentally and theoretically. A direct visualization of the magnetic landscape obtained by magneto-optical imaging on a Nb film is complemented by a multiscale numerical modeling. This combined approach allows the magnetic flux dynamics to be identified from the single flux quantum limit up to the macroscopic electromagnetic response. Within the theoretical framework provided by time-dependent Ginzburg-Landau simulations, an estimation of the in-plane current anisotropy is obtained and its dependence with the radius of curvature of hole vertices is addressed. Such simulations show that current crowding plays an important role in channeling flux motion, favoring hole-to-hole flux hopping rather than promoting interstitial flux displacement in between the holes. The resulting anisotropy of the critical current density gives rise to a distinct pattern of discontinuity lines for increasing and decreasing applied magnetic fields, in sharp contrast to the invariable patterns reported for centrosymmetric pinning potentials. This observation is partially accounted for by the rectification effect, as demonstrated by finite-element modeling. At low temperatures, where flux penetration is dominated by thermomagnetic instabilities, highly directional magnetic flux avalanches with a fingerlike shape are observed to propagate along the easy axis of the pinning potential. This morphology is reproduced by numerical simulations.

Magnetic nanocomposite aiming to silica nano-spicules production for viral inactivation in 3D printing surfaces

Anderson Gomes Vieira[1], Karina Maria de Souza Silva[1], Petrus Santa-Cruz[1], Antonio Carlos Pavão[1]

[1]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*)

e-mail: anderson.agv@ufpe.br

This work reports on the early stages of developing printable nanocomposites designed to inactivate viruses using silica nano-spicules involving magnetic nanoparticles (MNPs). This composite is formed of a photopolymerizable resin and a nanometric phase that, to be more hostile to viruses, must form artificial nano-spicules aiming at viral envelope damage. The methodology involved starts extracting magnetic nanoparticles from ferrofluids that were encapsulated with mesoporous silica in a star-shaped format (MNPs@SiO_2), as adapted from Zhang *et al.*(2013)[1]. These nano-spicules are expected to perforate the viral capsid and cause leakage of genetic material. The MNPs@SiO_2were dispersed in commercial photopolymerizable resins and printed in various formats using mask stereolithography (MSLA) printers with 405 nm LED sources. The printing parameters were evaluated to ensure the preservation of the 3D print quality. The samples were characterized using X-raydiffraction, atomic force microscopy, transmission, and scanning electron microscopy. Theresults showed that the nanocomposite was successfully prepared without affecting printability, and nanoparticles were attracted to the surface during printing. Finally, in collaboration with FIOCRUZ-PE (Aggeu Magalhães Institute), the antiviral action of the nanocomposites is being tested.

Magnetocaloric effect in compounds R_2Cu_2X (X=Cd,In).

Nilson Antunes de Oliveira[1], Julieth Caro Patiño[1] [1]Universidade

do Estado do Rio de Janeiro (*Instituto de Física*) *e-mail:*

nilson@uerj.br

The magnetocaloric effect, which is the basis of solid-state refrigeration is the cooling or heating of magnetic materials upon magnetic field variation. The magnetocaloric effect is commonly characterized by the entropy change in an isothermal process (ΔS_{iso}) and by the temperature change (ΔT_{ad}) in an adiabatic process. Despite the bunch of experimental and theoretical works already published in the literature, a complete understanding of the physics behind the magnetocaloric effect is still lacking. The search for new magnetic materials with large values of the magnetocaloric quantities as well as new thermodynamic methods are some challenges in this area of research. In this paper, we discuss, from the theoretical point of view, the magnetocaloric effect in the series of compounds R_2Cu2X, where R stands for rare earth elements and X=Cd, In. For this purpose, we use a Heisenberg-like Hamiltonian with two magnetic sublattices and adopt the mean-field theory to treat the interactions between local magnetic moments. Our calculations show that the magnetocaloric quantities $\Delta S_{iso}$and ΔT_{ad}in the compounds Gd_2Cu_2Cd, Er_2Cu_2Cd, andTb_2Cu_2Cd show the usual behavior, i.e. they reach a sharp peak around the temperature ofthe phase transition and go down as the temperature moves from the critical region. On theother hand, in the compounds Dy_2Cu_2Cd Dy_2Cu_2In the curves of the magnetocaloric quantities exhibit two peaks which can be associated with two types of phase transitions. This fact, which is in good agreement with the available experimental data, is indeed due toan antiferromagnetic behavior observed in these compounds.

Permalloy nanowires growth by Haberland-type gas aggregation source

Claudio Alejandro Gonzalez Fuentes[1], Christian Orellana[2], Maria Abellan[3], Rodrigo Segura[4], Christian Romero[2]

[1]Universidad de Santiago de Chile (*Física*) , [2]Universidad Técnica Federico Santa María (*Física*) , [3]Universidad Técnica Federico Santa María, [4]Universidad de Valparaíso (*Química*)

e-mail: claudio.gonzalez.f@usach.cl

Gas aggregation method is a widely employed technique to fabricate nanostructures, however, it faces several challenges to improve the output efficiency. One of them is the loss of species that occur within the aggregation chamber, mainly caused by entrapment zones. In the present work, Permalloy Ni80Fe20 nanostructures were grown on a silicon substrate by a Haberland-type gas aggregation source, following a singular synthesis strategy consisting in placing the substrates inside the aggregation chamber, with the idea of recovering lost species at the entrapment zone. The nanostructures obtained are made up of nano-chains grouped into microfibers with a certain preferential growth orientation and characterized by lengths of the order of micrometers and diameters between 500 and 20 nanometers. Furthermore, these nanostructures were characterized by X-ray diffraction, scanning electron microscopy, and magnetic response.

Skyrmion dynamics in the presence of defects inPd/Fe/Ir

Pamela Costa Carvalho[1], Angela Burlamaqui Klautau[2], Helena Maria Petrilli[1], Anders Bergman[3]

[1]Universidade de São Paulo (*Instituto de Física*) , [2]Universidade Federal do Pará (*Faculdade de Física*) , [3]Uppsala University / Uppsala Universitet (*Materials Theory*)

e-mail: pamela.costa.carvalho@usp.br

Magnetic skyrmions are noncollinear nanostructures which can be used as an information carrier in the design of new magnetic storage devices. Due to its topological feature, skyrmions can behave as particles, where they can be easily manipulated through the application of a polarized current density, for instance. Nonetheless, the current-induced motion of skyrmions has been experimentally investigated and different behavior for individual skyrmions were attributed to the presence of defects at the material [1]. Then, in order for these nanostructures to be realistically applied in new technologies, it is important to understand the skyrmions motion in the presence of inhomogeneities. In the literature, studies have been conducted regarding skyrmions’ dynamics with impurities, where gyrotropic motion, deflection and pinning behaviors were found according to attractive or repelling defects [2]. However, to the best of our knowledge, the effects of interfacial intermixing of atoms, in the skyrmions’ motion, has not been explored in the literature yet, specially a random distribution of defects. In this work, we use the Pd/Fe/Ir multilayer as our object of study to investigate skyrmions’ dynamics in the presence of intermixing of atoms at the interfaces Pd/Fe and Fe/Ir. From first-principles converged electronic structure results and magnetic interactions, the skyrmions’ motion is simulated through atomistic spin dynamics [3] with a polarized spin current density. Here, we consider several possibilities of intermixing, such as Pd and Ir atoms at the Fe layer, and analyze the type of motion as a function of the current density, initial position and percentage of defects.

Study of magnetic nanoparticles produced on hollow cathode magnetron sputtering gun

Rodrigo Dias Garcia[1], Antonio Domingues Santos[1]

[1]Instituto de Física da Universidade de São Paulo (*FTM*) *e-mail: rdgarcia@usp.br*

The development of new methods for nanoparticles production has been one of the focal points in the recent years on material science research. This work consists of the development of a physical method for the production of magnetic nanoparticles (NPs). Here, we are using a new radial magnetron sputtering (RMS) gun, and the gas aggregation method. This RMS gun was developed and constructed in our lab and represents a improvement over the planar magnetron sputtering gun. In the setup, samples were prepared in the NP gun, installed as a new gun on a commercial magnetron sputtering system. Typically, the sputtering system operates at a pressure of 5 mTorr in the main chamber. However, inside the NP gun there is a pressure of 780 mTorr, under the Ar flux of 80 sccm. Atoms removed from the target are thermalized by the Ar flux and condensed to form NPs, which are extracted from the NP gun aerodynamically, flowing in direction to the substrate. The device is capable of producing films of NPs of different metals, including ferromagnetic metals, and also co-deposit the NPs simultaneously with other sputtered film. Cu and Co NPs were produced. For Cu NPs the averaged diameter was 5.79(8) nm and standard deviation of 2.97(5) nm, with crystallinity compatible with the FCC structure. Co NPs presented an average diameter of 3.88(3) nm and standard deviation of 1.74(2) nm, with crystallinity compatible with the FCC and HCP structures. When co-deposited with Si3N4 film, the agglomeration of NPs on substrate was minimized and Co NPs samples showed superparamagnetic behavior. This behavior was described by a combination of Langevin function and a distribution of diameters. Co NPs film dispersed with capping and buffer layer of Si3N4 showed average diameter of 3.1(1) nm and standard deviation of 1.2(1) nm. Co NPs film covered with Si3N4 showed average diameter of 3.8(2) nm and standard deviation of 2.2(2) nm. Both samples showed aging, with a loss of 66% of Co NPs, after one week.

Supercurrent diode effect and anisotropic vortex squeezing in non-centrosymmetric Rashba superconductors

Denis Kochan[1]

[1]Slovak Academy of Sciences (*Institute of Physics*)

e-mail: denis.kochan@savba.sk

Most of 2D superconductors are of type II, i.e., they are penetrated by quantized vortices when exposed to out-of-plane magnetic fields. In a presence of a supercurrent, a Lorentz-like force acts on the vortices, leading to drift and dissipation. The current-induced vortex motion is impeded by pinning at defects. Usually, the pinning strength decreases upon any type of pair-breaking interaction perturbs a system.

In the talk I will discuss surprising experimental evidences showing an unexpected enhancement of pinning in synthetic Rashba 2D superconductors when applying an in-plane magnetic field. When rotating the in-plane component of the field with respect to the driving current, the vortex inductance turns out to be highly anisotropic. We explain this phenomenon as a direct manifestation of Lifshitz invariant that is allowed in the Ginzburg-Landau free energy when space-inversion and time-reversal symmetries are broken. As demonstrated in our experiment [Physical Review X 12 (4), 041020 (2022)], elliptic squeezing of vortices---an inherent property of the non-centrosymmetric superconducting condensate---provides an access to fundamentally new property of Rashba superconductors, and offers an entirely novel approach to vortex manipulation.

Another interesting feature of the non-centrosymmetric superconductors in the applied magnetic field is the supercurrent diode effect---the critical current in one direction exceeds its counterpart in the opposite one---what stems from the Cooper pairs with finite centre of mass momentum. In the pioneering experiment [Nature Nanotechnology 17 (1), 39 (2022)] we demonstrated the emergence of the supercurrent diode effect in the Josephson junctions based on synthetic Rashba superconductors made of Al-InAs quantum wells. In the talk, I will discuss novel experimental method---measurements of the Josephson inductance---and the semiquantitative microscopic model capturing all the essential features as observed in experiment.

Tailoring CeO2 Nanoparticles via Microwave-Assisted Hydrothermal Synthesis

Ronei C. Oliveira[1], Ailton José Moreira[2], Ernesto Chaves Pereira de Souza[2], Adilson J A de Oliveira[1]

[1]Federal University of Sao Carlos (*Física*) , [2]Federal University of Sao Carlos (*Química*)

e-mail: ronei.physics@gmail.com

The influence of synthesis conditions on morphology and structure of CeO_2nanocrystals prepared by microwave-assisted hydrothermal method were studied by XRD, SEM and diffuse reflectance measurements. Decisive effect of the OH^-/Ce^{3+}molar ratio in the reaction mixture on the size and shape of CeO_2nanocrystals was established. Higher concentration of OH^-ions in the growth solution promotes bigger crystallite sizes as well as shape transformation from irregular (spheroidal) to needle-like and a mixture of needle-like and cubic nanoparticles. A difference in the energy gap was also observed, which can be attributed to differences in the oxygen vacancy concentration of the CeO_2nanoparticles, which is known to be influenced by the synthesis conditions [1]. Our results demonstrate that the MAHT method is an effective route to synthesize CeO_2nanoparticles with high crystalline quality and tailored morphology, where the molar ratio between precursors is crucial for controlling crystallite size and shape. These findings are valuable for the design and development of efficient catalysts, energy storage devices, and biomedical applications that require tailored magnetic properties.

The role of Tb, Dy and Ho intercalations on the superconducting and magnetic properties of $ZrTe_3$

Leandro Rodrigues de Faria[1], Fabio Abud[1], Lucas Eduardo Correa[2], Milton Torikachvili[3],
Antonio jefferson da silva machado[1]

e-mail: leandro.rf@usp.br

$ZrTe_3$ is a well-known monoclinic Van der Waals material with a highly anisotropic behavior emerging from a combination of quasi-one-dimensional electron-like sheets along with a three-dimensional hole-like sheet at the Fermi level. This combination of bands gives rise toa Charge Density Wave (CDW) ordering at 63 K, which coexists with superconductivity emerging at 2.0 K. The superconducting transition temperature (T_c) may be raised as the CDW is suppressed through atomic disorder, substitutional doping with selenium or intercalation with transition metals. In the latter, T_c more than doubles through intercalation of Cu, Ni or Ag with transition temperatures ranging from 3.8 to 4.6 K. Among the transition metals, Ni is the only magnetic intercalant that raises T_c, while intercalation of Fe was shown to be detrimental to superconductivity with the development of an antiferromagnetic order. Such diverse effect of the magnetic intercalant leaves a question open on what role the electrons of isolated inner shells may play on the properties of $ZrTe_3$, and the intercalation of elements with incomplete *f* electron shells may be a reliable way to study this aspect of the superconducting ground state. We successfully intercalated Terbium, Dysprosium and Holmium into $ZrTe_3$ single crystals with resulting transition temperatures in the vicinities of 5.3 K, along with a raise in susceptibility and signatures of antiferromagnetic order in all samples. The effects of the different rare-earth metals on the superconducting properties are compared by means of resistivity, magnetization and thermoelectric power measurements.

Superconducting weak links (WLs) give rise to exciting phenomena, paving the way for efficient electronics that integrate with the most advanced quantum technologies. Thus, patterning of superconducting films has become an essential process. However, introducing regions of suppressed superconductivity leads to a reduction of the device's critical current. In a previous report [1], we investigated the effects of a single groove-like WL created by Focused Ion Beam (FIB) milling in the properties of the normal and superconducting states of 180-nm-thick Nb films, revealing unexpected local peaks in their magnetization hysteresis loop. In this work [2], we explain such a phenomenon by exploring Magneto-Optical Imaging (MOI) to its full potential, locally quantifying magnetic and transport properties of the nanostructured Nb films. By mapping the magnetic flux distribution, we reveal that the local peaks are accompanied by a transformation of the sample's current domains. This process indicates a magnetic field-mediated increase in the WL critical current density (J_c^{WL}), quantitatively confirmed by MOI. To that effect, we reveal that the WL may behave as a strong link, allowing supercurrents to flow through it almost unaffectedly. By quantifying the flux inside and outside the film, we determine the vortex dynamics responsible for the J_c^{WL} enhancement and how it relates to the nanofabrication process. These results are corroborated by thermomagnetic model simulations. These effects bear a close resemblance to observations in high-temperature superconductors and may be used to enhance the performance of superconducting devices and in the development of new electronic applications.

Zero-field magnetic skyrmions in symmetric Pt/Co synthetic antiferromagnetic multilayers

Lucas Scaranari Palhares[1,2], Jeovani Brandão[1], Fanny Béron[2]

[1]Brazilian Center for Research in Energy and Materials (*LNLS*) , [2]University of Campinas (*LMBT/DFMC/IFGW*)

e-mail: palhares@ifi.unicamp.br

Magnetic skyrmions are topological solitons, emerging in the spin texture of magnetic systems without spatial inversion symmetry, such as non-centrossimetric crystals and multilayered thin films [1]. Skyrmion states exhibit a vortex-like spin structure with non-trivial topology, which gives the canted texture high stability and enable interesting spintronic applications. Skyrmion phases exist under narrow intervals of temperature and external magnetic field, hindering applications that require ambient conditions. Synthetic Antiferromagnetic Multilayers (SAF-MLs) are systems showing antiferromagnetic behavior, due to the antiparallel magnetization coupling of two ferromagnetic layers through a non-magnetic spacer layer, that have been reported as a skyrmion-hosting material in such conditions [2,3].

Here, we present experimental results of symmetric Pt/Co/Ru/Co/Pt multilayers, with varying Ru spacer thickness (t_{Ru}), by combining magnetometry measurements with magnetic force microscopy (MFM) imaging. The coupling energy was probed and correlated to the observed spin texture. Specifically, the hysteresis curves indicate three distinct types of SAF behavior for t_{Ru}= 0.4, 0.6, and 0.8 nm, exhibiting high saturation fields and very low remanence. Furthermore, MFM images indicates that the spin texture prior to magnetic field application is a mixed state containing worm-like stripes and skyrmions, while the remanent state texture reveals isolated skyrmions. These results show that skyrmions are present in compensated symmetric SAF–MLs under zero-field and room-temperature conditions, contributing to the realization of skyrmion-based spintronic devices.

Ab initio study of Pd/Fe/Ir(111) bilayers decorated with Co nanostructures

Juan German Cornelio Palma[1], Pamela Costa Carvalho[2], Helena Maria Petrilli[2], Angela Burlamaqui Klautau[3]

[1]Instituto de Física/USP (*Física de Materiais*) , [2]Universidade de São Paulo (*Instituto de Física*) , [3]Universidade Federal do Pará (*Faculdade de Física*)

e-mail: juangcoeneliopalma@gmail.com

The study of skyrmions in recent decades has been of fundamental importance in the development of the next generation of information storage devices based on spintronics. However, before the complete implementation of this concept in technology, several challenges still need to be resolved. One such challenge is the Skyrmion Hall Effect, which results in the annihilation of the topological structure at the boundaries of the racetrack memory. Another problem is the difficulty in stabilizing skyrmions in the absence of a magnetic field. Experimental work conducted by J. Stephman et al. [1] shows that decorating the film edge of Pd/Fe/Ir(111) multilayers with Co/Fe patches can prevent skyrmion annihilation at the film edge and stabilize zero-field skyrmions and target states. In the present study, our aim is to provide theoretical support for the studied system. We investigate the electronic structure of different geometrical configurations of Co nanoislands in the Pd layer, with a focus on their magnetic properties. This study is conducted using first-principles calculations within the framework of the Density Functional Theory (DFT) [2], specifically utilizing the Real Space Linear Muffin-Tin Orbital in the Atomic Sphere Approximation (RS-LMTO-ASA) [3] within the Local Spin Density Approximation (LSDA). The use of a real space method presents advantages in treating systems with broken symmetry, such as the simulation of impurities and defects.

$SrFeO_3$(SFO) material is an oxide semiconductor with unpaired electrons on the Fe atoms as an advanced material in electronic properties and antiferromagnetic ordering. The SFO material is a cubic Perovskite with space group Pm-3m [1] with many possibilities of chemical modifications, for example, doping in Sr and Fe atoms, and presence of O vacancy [2]. The computational simulations were performed on DFT/HSE06 level in CRYSTAL17 software. The Sr, Fe, O, and Ag atoms were described by HAYWSC-311(d11f)G, 86-411d41G, 8-411d11G and 97-66314d(11) Gaussian-type basis sets, respectively. The $Ag_{0.25}Sr_{0.75}FeO_{2.875}$ (ASFO) material was simulated in a 2x2x2 supercell in two structures: i) the Ag doping on center and corner positions (ASFO-C); ii) the Ag doping on center and face positions (ASFO-F), including the O vacancy in both materials.

From the Ag doping in SFO structure, ASFO-C and ASFO-F models, showed distortions on the c lattice parameters. The $[FeO_6]$ octahedrons structures presented perturbations on the intermetallic angles (Fe-O-Fe) because of the modifications on the volumes, widely reported in literature as Breathing Distortions [3]. The SFO material presented a metallic electronic profile for conduction property, while the ASFO-C and ASFO-F materials, the Ag doping and the O vacancy, became the electronic profiles as half-metallic behavior, with bandgap of 1.70 eV in both materials. The SCDM showed distortions on the spin density of Fe atoms, and the phenomena of spin canting, denoting an anisotropic electronic behavior.

e-mail: mmacorrea@gmail.com

Recent advances in the field of spintronics have stimulated interest in phenomena involving thermal and magnetic features, hence driving researches on their potential of application in green energy devices. Within this context, the Anomalous Nernst Effect (ANE) in nanostructured magnetic materials appears as a key phenomenon to optimally control and employ the internal energy dissipated in electronic devices, being dependent on, for instance, the magnetic anisotropy of the active element. In biphase magnetic systems, owing to the interplay of the distinct (hard/soft) magnetic properties, the dependence of theANE with the magnetization opens doors to quite-promising possibilities to manipulate the thermoelectric response by changing the magnetic anisotropies. Here we report an investigation of the structural features, magnetic properties and ANE in a NiFe/Cr/NiFe trilayer. We observe that the distinct structural properties of the bottom and top magnetic layers lead to the biphase magnetic behavior. We verify the ANE measurements have remarkable dependence with the anisotropies and magnetic response. Thermoelectric results seem to be very sensitive to the anisotropy of the biphase system than the magnetization ones, revealing interesting features of the magnetization process and placing place the ANE experiments as a very-sensitive tool to characterize anisotropic magnetic systems. In addition, the themoelectric experiments help us to understand the role of each layer in the ANE response for biphase systems, opening new perspectives to explore such systems for current and future technological applications.

Comparative Local Analysis of Ni/Ni3C Nanoparticles Synthed with Oleylamine/Oleic Acid and Oleylamine/Palm Kernel Oil Ligand Pairs: Structural and Magnetic Properties.

Crystian Wilian Campos da Silva[1,2], Larissa Otubo[3,2], Katiusse Soares de Souza[1,2], Artur Wilson Carbonari[1,2], Bruno Santos Correa[1,2], Rafael Sá de Freitas[4], Gabriel Adolfo Pasca[5], Cleidilane Sena Costa[5]

e-mail: Crystianwill@usp.br

In recent decades, Ni/Ni3C nanoparticles have been a topic of interest, especially for their catalytic and magnetic properties, promising as electrocatalysis, for example [1]. These systems are usually obtained by chemical methods, in the presence of ligands responsible for controlling their structure and morphology [2]. In this work, we carried out a comparative study of the hyperfine interactions occurring in Ni/Ni3C nanoparticles, synthed by thermal decomposition in the presence of oleylamine/oleic acid and oleylamine/palm kernel oil ligand pairs, at 513 K, for 3 hours. The local analysis was performed using perturbed correlation spectroscopy (PAC) in the temperature range from 30K to 300K, using the 111Cd probe, implanted in the samples by diffusion, during the synthesis. The parameters of the hyperfine interactions were compared to the results obtained by XRD, TEM and magnetization, indicating the obtainment of Ni/Ni3c nanoparticles of the core-shell type, showing a higher Ni3C content, greater distribution and lower saturation magnetization for nanoparticles synthed with palm kernel oil compared to those obtained with oleic acid. In addition, the hyperfine parameters showed the existence of regions with a quadrupole frequency of 24 MHz and a magnetic hyperfine field of 1T in both samples, which may be indicative of carbon-deficient Ni3C regions, predicted in the literature [3].

e-mail: adriana.soarescarvalho@ufpe.br

Graphene-based materials are known for their advanced properties, such as high area-to-mass ratio, electrical conductivity and capability to modulate their own properties through structural doping [1]. This capability makes these materials versatile and adjustable to current technological needs. Doping can also be adopted as an anchoring site for other nanostructures, which can be used for applications according to their nature [2]. In this context, nitrogen-doped graphene (NrGO) based aerogel were synthed through the hydrothermal method. NrGO were used as a spongy matrix for absorbing the aqueous suspension of magnetite nanoparticles (Fe_3O_4-NPs), forming the Fe_3O_4@NrGO composite. Also, Fe_3O_4@rGO was produced, used as a point of comparison to investigate the nitrogen doping effects on the structure of graphene and its influence on the magnetism of the composites. The Fe_3O_4-NPs showed superparamagnetic character (~5 nm by Scherrer equation). We expect that the NPs were anchored by physisorption in the NrGO structure, which presented an amount of 40.51 at% N-pyrrole by X-ray photoelectron spectroscopy (XPS). The composites were characterised by vibrating-sample magnetometry (VSM) and electron paramagnetic resonance (EPR) spectroscopy. The Fe_3O_4@NrGO presented saturation magnetization (M_S) of 0.7219 emu/g, more than twice higher than Fe_3O_4@rGO. We associate this effect to the expected higher hydrophilicity in NrGO, due to H-bonding interactions with nitrogen. The enhanced wettability should allow greater penetration of the Fe_3O_4-NPs suspension and greater incorporation of nanoparticles in NrGO. Low-field resonant peaks can be associated with the nitrogen paramagnetic centres of the NrGO, promoting efficient anchoring of Fe_3O_4-NPs.

Conventional s-wave superconductivity in non-centrosymmetric Re_3M (M = W, Ta, Nb) solid solutions.

Fabio Santos Alves Abud[1,2], Nabil Chaia[3], Milton Torikachvili[4], Renato de Figueiredo Jardim[2]

e-mail: fabio.abud@usp.br

Weakly correlated, rhenium-rich superconducting compounds crystallize in a non-centrosymmetric structure and are potential candidates to host both singlet and triplet superconducting states. However, conventional BCS s-wave order parameter were reported in many of those materials, with some also breaking the time-reversal symmetry in the superconducting state. In this work, we study Re_3M (M = W, Nb, Ta) compounds that crystallize in the non-centrosymmetric cubic α-Mn (or A12) structure and have superconducting critical temperatures $T_c$ranging from ~ 4 to 9 K. Polycrystalline samples of Re_3M and its solid solutions, where one M is partially substituted for another, were synthed by arc-melting and heat treated subsequently at 1700 °C in vacuum. Motivated by the stability of the α-Mn structure in the Re-Ta and Re-Nb systems, we substituted partially Ta and Nb for W, leading to single phase NCS $Re_3W_{0.5}Ta_{0.5}$and $Re_3W_{0.5}Nb_{0.5}$even in as-casted samples, unlike the parent Re_3W compound. In what pertains to the superconducting properties, the low temperature heat capacity $C_p(T)$ data suggest conventional s-wave pairing in all samples [1], which is also supported by magnetization M(T), electrical resistivity $\rho(T)$, and thermal conductivity $\kappa(T)$ measurements. The estimated upper critical fields $H_{c2}(0)$, however, are sizable in comparison with the Pauli limiting field. These results are discussed within the context of the emergence of superconductivity in non-centrosymmetric materials.

Multiferroic materials have been under the spotlight due to their fundamental scientific interest and for potential applications in technology. Among these interesting materials are the group of compounds belonging to the Pyroxene family with general chemical formula AM(Si,Ge)$_2$O$_6$. More specifically, SrMnGe$_2$O$_6$[1]and CaMnGe$_2$O$_6$[2]are isostructural, crystallizing with monoclinic C2/c symmetry and are characterized by zigzag chains of MnO$_6$ octahedra linked by edge-sharing, separated by corner-sharing GeO$_4$ tetrahedra chains along the same axis. Due to this arrangement these systems present a rich diversity of low-dimensional magnetic properties.

In this work the structural and electronic properties of the CaMnGe$_2$O$_6$and SrMnGe$_2$O$_6$ clinopyroxene systems have been investigated by means of Perturbed Angular Correlation (PAC) measurements and Density Functional Theory (DFT) calculations using Quantum ESPRESSO [3], including a comparative analysis between the experimental electric field gradients and theoretical values obtained from DFT calculations. The enthalpies of formation of the constituent oxides of the broader AMnGe$_2$O$_6$(A = Be, Mg, Ca, Sr) series have also been examined through DFT calculations.

Magnetic carbon nanotubes (Fe3O4-CNT) have advantages in determining metals via magnetic solid phase extraction systems, optimizing sample preparation. Surface modifications enhance absorptive capacity in complex matrices through protein mobilization, reducing competition for active sites. Restricted access materials (RAM) have shown great results for the determination of toxic metals in complex matrices [1]. This work objective is the use of Fe3O4-MWCNT coated with bovine serum albumin (BSA), for the determination of zinc, copper and lead in food supplements, by FAAS. The material was magnetized by addition of MWCNT to a suspension of Fe3O4 in ethanol, the reaction was maintained in inert atmosphere and stirring for 4 hours. For BSA immobilization, were used solutions of BSA in phosphate buffer, glutaraldehyde, and borohydride, which were separately added to the material, stirred, left to rest, and discarded, then, washed with ultrapure water. From ATR-FTIR spectrum, peaks at 1525 cm-1 and 1641 cm-1 indicates the presence of functional groups of BSA protein, as such, N-H, C-N (tyrosine) and N-H (amide). The BET isotherm showed that specific area was 105.3 g.m2, the pore volume and were 0.2119 cm3 and 10.51 nm, respectively, implying that the MWCNT modifications did not change textural properties, for this class of materials [2]. For quantification of zinc, copper and lead in aqueous standards solutions, the material showed a 34-fold gain in signal for the determination of Zn2+ (50µg. L-1, pH 8.0), while for Pb2+ (200µg. L-1, pH 6.0) and for Cu2+ (200µg.L-1, pH 8.0) the gain in signal were 20 and 16 times, respectively. Studies arebeing made to optimize the parameters that affect the magnetic solid phase extraction, to beapplied later in food supplements samples.

Using magneto-optical techniques for characterizing magnetic materials is a well-known approach which benefits from versatility and simplicity. For better exploring the potential of this technique, a data acquisition and signal processing program was developed for a magnetometer based on Magneto-Optical Kerr Effect (MOKE). This program was developed in the Labview language and it was used for interfacing our magnetometer and analyzing the acquired data. The program communicates with the system's instruments [1]: lock-in amplifiers, multimeters, current power supply, sensors, diode laser source (670nm) and others optical components. It's possible within the program to set signals profiles as input [2]: waveforms, maximum levels, resolutions and repetition cycles. As outputs, graphs of the results (hysteresis curve) and selectable numeric data, that can be exported as text formatto data analysis software. Through the configuration of optical components and program outputs, the user can characterize the magnetic properties of samples, characterizing some of its important features such as anisotropy, magnetic coercivity and remanence. The program provides programmable cycles of demagnetizations and it’s easily updated according to need and specific measurement/scientific goals. In addition, part of the existing system is already being used for time-resolved analyzes (TRMOKE) for the Kerr effect and also for the Faraday effect, covering, in this way, new possibilities of characterizing dynamical magnetic properties which is of interest for the development of devices allowing operation into the terahertz range.

The electronic superexchange described by Goodenough-Kanamori-Anderson (GKA model) [1] indicates that the magnetic coupling behavior between two magnetic sites intermediated by non-magnetic barrier as an O atom. In a Pm-3m cubic crystallographic arrangement, this material is a challenge to understand the GKA model. The HSE06 functional in DFT quantum simulations was performed from the CRYSTAL17. The HAYWSC-311(d11f)G, 86-411d41G and 8-411d11G gaussian basis sets descriptions were implemented for the Sr,Fe and O respectively. A 1x1x2 supercell built two [FeO6] magnetic clusters to investigateFM and AFM the magnetic ordering on the [Fe-O-Fe] connection under oxygen vacancy (Vo) perturbation. To evaluate the electronic profiles, the Electronic Band Structure (EBS) and Density of States (DOS) were discussed.

Structural data for the crystalline structure showed lattice parameters in agreement with experimental data in literature [2]. The magnetic ordering obtained to SFO structure simulated follows the literature, where is reported an AFM magnetic ordering to material. From the Vo perturbation, SFO:VO material, was noted that the Vo preserved the AFM ordering. The EBS presents a metallic behavior for the SFO material, and in the SFO:VO material, the Vo switch to a semiconductor material. Then, the overlap on between these electronic states shows an important interaction in intermetallic bond discussed as a molecular path for the GKA model, where SFO and SFO:Vo materials have a intense superexchange effect between Fe atoms an O non-magnetic atom acting like a bridge to interaction of two magnetic clusters.

Diluted magnetic semiconductors (DMS) are a class of materials that exhibit unique magneto-optical properties that can be tuned by adjusting the dopant concentration. They are produced by incorporating magnetic ions, typically transition metal(TM) ions, into semiconductor hosts. The presence of these magnetic ions gives rise to DMS having a range of potential applications, including spintronics, magnetic sensors, and information storage[1-3]. Despite this, few studies in the literature have examined how the locations ofTM ions influence the structural and optical characteristics of titanium dioxide(TiO_2) nanocrystals. $TiO_2$is a semiconductor with ultraviolet absorption and emission,photostability,catalytic and osseointegration properties[4].In this study, the effect of iron ion concentration on the properties of TiO_2nanocrystals was investigated. The magnetic, structural, morphological and optical properties were analyzed using Magnetization, Electronic Resonance Paramagnetic, X-ray Diffraction, Raman Spectroscopy, Scanning Electron Microscopy and Optical Absorption Spectroscopy.XRD diffractograms and Raman spectra confirmed the formation of TiO_2 nanocrystals in the anatase phase.Additionally, the formation of other crystals was not observed. SEM images confirmed that the crystals were in the nanometer scale.In the AO spectra, the incorporation of Fe ions into the crystalline lattice of the TiO_2nanocrystals was verified by the variation of the band gap and the presence of characteristic absorption bands.To determine the locations where Fe ions were substituted for Ti ions, the Crystal Field Theory was utilized.Using the Tanabe-Sugano diagrams, it was demonstrated that Fe ions were integrated into tetrahedral and octahedral sites of the TiO_2NCs, depending on the doping concentration.The Mz and EPR results demonstrate the presence of Fe ions and how the concentration altered the magnetic properties.

Effect of reaction on the microstructure and superconductivity in Bi/Ni Nanoparticle/Thin FilmSystems

Superconductivity in Bi-Ni bi-layer system attracted great attention because both Ni and crystalline Bi are non-superconducting above 50 mK and no agreement has been made for the interpretation. We studied the bilayers of Bi-Ni and concluded that the superconductivity is from the formation of the $NiBi_3$or NiBi intermetallic compounds. Atom diffusion is highly involved in the reaction of Ni and Bi [1,2]. To give more evidence to this conclusion, we studied hybrid systems with Bi thin film (TF) layer and Ni nanoparticles (NPs) on top, or Ni layers with Bi nanoparticles on top. The NPs of Ni or Bi are formed before depositing on the layers and the activity of the atoms in NPs is much smaller than the single atoms. In this case the diffusion would be more difficult to occur. The TEM images and the diffraction patterns of the hybrid samples indicate that Ni reacted with Bi in all samples and formed the intermetallic compounds $NiBi_3$. Pure Bi and Ni remains in samples of Ni NPs deposited on Bi. On the other hand, the Ni TF deposited on the Bi NPs does not show the existence of pure Ni. Electrical transport measurements indicate that Ni TF samples deposited on Bi TF shows the narrowest and most complete superconducting transitio the Ni NP samples deposited in the Bi TF, however, shows the widest and most incomplete superconducting transition due to more difficulty of reaction when depositing NPs of Ni atoms on Bi. The reaction of Bi and Ni induced the agglomeration of Bi and generated inhomogeneity in the thickness of the samples. The results strongly support the conclusion that superconductivity is from the intermetallic $NiBi_3$formed by the reaction of Ni and Bi.

Noble metal nano-heterostructures in combination with iron oxide have aroused great interest due to their multiple modifiable surfaces, unique magnetic properties and biocompatibility, making them promising for effective biomedical applications such as magnetic fluid hyperthermia (MFH). MFH selectively destroys or weakeni malignant tumor cells by increasing their temperature above a critical value. However, a challenge to be overcome is the limited heating capacity or low specific absorption rate (SPA) of the NPs. To improve the heating efficiency, researchers have employed strategies such as enhancing anisotropy, varying volume, developing core-shell structures, among others. In this work, we will present a study of the structural, morphological, and magnetic characterization of Au/Fe304 hybrid NPs and their corresponding ferrofluids explored for MFH applications. The influence of the gold core and the magnetic response of the magnetic shell will be systematically studied. Although many studies have been carried out with iron oxide NPs, the potential of the Au/Fe304 combination has not been systematically explored. The Au/Fe304 NPs were prepared by thermal decomposition of iron precursors in the presence of pre-formed ~7 nm Au seeds. The crystal structure and morphology of the NPs were determined by X-ray Diffraction (XRD), Transmission Electron Microscopy (TEM), and magnetic properties were determined by magnetization measurements. The SPA was obtained for different NPs concentrations dispersions and in different rheological conditions (i.e., different fluid viscosities), with frequencies between 100 kHz and 800 kHz and magnetic field amplitude of up to 56 mT. The resulting SPA values were analyzed in terms of the different possible mechanisms that determine the magnetic losses. This review will provide information on structure control in tuning the function of heterogeneous or hybrid materials in the study of magnetic fluid hyperthermia.

Enhanced spin Seebeck effect in the paramagneticphase of the three-dimensional Heisenberg antiferromagnet $RbMnF_3$

José Diêgo M. de Lima[1], Pablo R. T. Ribeiro[1], Fernando L. A. Machado[1], Sergio M. Rezende[1]

[1]Universidade Federal de Pernambuco

e-mail: marques.lima@ufpe.br

$RbMnF_3$ is an insulating antiferromagnet with a perovskite crystal structure and Néel temperature $T_N = 83$ K. Having magnetic ions with a S electronic ground state in a cubic arrangement, its magnetic anisotropy vanishes so that it is a nearly perfect three-dimensional Heisenberg antiferromagnet. Here, we report measurements of the spin Seebeck effect (SSE) in bulk samples of $RbMnF_3$ with the shape of a slab onto which a thin Pt film strip is deposited. By applying a thermal gradient perpendicular to the slab plane, we detect an electric voltage along the Pt strip due to the charge current resulting from the conversion of the thermally generated spin current by means of the inverse spin Hall effect. By varying the magnetic field applied on the plane of the slab, we observe the antisymmetric step variation typical of the SSE both in the spin-flop and paramagnetic phases. Surprisingly the SSE increases with temperature in the paramagnetic phase and becomes comparable to the one in the ordered phase. This enhancement is attributed to a combination of the free spin fluctuations of paramagnetic insulators with the thermal conduction of long-lived paramagnons made possible by the short-range order that persists above T_N.

Estimate of weight-to-power ratio of a Tesla-type thermomagnetic motor

Eduardo Henrique Gomes Evaristo[1], Oswaldo Horikawa[1], Carlos Vinicius Xavier Bessa[2]

[1]Universidade de São Paulo (*Mechanical Engineering Department*) , [2]Universidade CatólicaDom Bosco (*Mechanical Engineering Department*)

e-mail: ehgevaristo@usp.br

Thermomagnetic motors (TMs) are a class of devices focused on obtaining mechanical work exploiting the magnetic phase transition of a working material (WM), when submitted to a temperature change around its Curie temperature (Tc). An important factor of such devices is the weight-to-power generation ratio. Seeking to estimate such ratio, an interpolation study of the theoretical results presented in [1] was made for a Tesla-type TM, which undergoes a magnetic Brayton cycle (MBC). Using the data of specific work per cycle from [1], two scenarios were considered: (a) the mass of WM required to produce 1kW of mechanical power; (b) the power produced with 1kg of WM. This was investigated for different conditions of temperature around Tc. It was considered an uniform temperature distribution along the WM and an applied magnetic field change of 1.5 T. Demagnetization effects were ignored and the cycle times were imposed. Two materials, with first and second order magnetic transition, respectively, were considered as WMs: MnAs and Gd. In (a), smaller cycle times required less mass of WM to generate 1kW. Gd requires much more mass and has a larger mass span over the values of ΔT when compared with MnAs. In (b), as expected, for the same value of mass, MnAs generates greater values of power then Gd. It is important to highlight that the permanent magnets mass was not taken into account. However, as a first estimate, these results can be used to get an order of magnitude of the size and weight-to-power ratio of TM undergoing a MBC.

e-mail: llbrandao@outlook.com

Microalgae biofuel is of great promise, but extracting their macronutrients is challenging given the thickness of their cell walls [1]. The enzymatic hydrolysis of cellulose can break them down, but this process is unprofitable on account of the enzyme' s poor stability and efficiency [1,2]. A practical and efficient solution to improve its stability is the immobilization of cellulase on magnetic nanoparticles (MNPs), which also allows for its recovery and reutilization [1,2]. Thus, this work sought to test the synthesis and functionalization of MNPs and the immobilization of cellulase on their surface. The MNPs were synthed by reducing iron salts in an alkaline medium, coated with tetraethyl orthosilicate (TEOS), and functionalized with (3-aminopropyl)triethoxysilane (APTS) and (3-mercaptopropyl)trimethoxysilane (MPTS). They were then characterized by transmission electron microscopy (TEM), Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, X-ray diffraction (XRD), and UV-Visible absorption spectroscopy, showing strong magnetization [3]. Once resuspended in a cellulase solution, the bioconjugation assay results revealed that the MNPs coated with TEOS, functionalized with APTS, and activated with glutaraldehyde showed the highest rate of cellulase immobilization, achieving a recovery of 250 mg/g of MNPs in just 1 hour.

Fe_3O_4 magnetic nanoparticles for Magnetic Fluid Hyperthermia

Gustavo Soares da Silva[1], Adriele Aparecida de Almeida[1], Diego Muraca[1]

[1]Gleb Wataghin Physics Institute, University of Campinas

e-mail: g235991@dac.unicamp.br

Magnetic hyperthermia is the conversion method of electromagnetic field energy into heat through magnetic nanoparticles (MNPs), i.e., when an external AC magnetic field (RF range) is applied to the nanoparticle magnetic colloids, energy in the form of heat is dissipated into the medium. Quantification of this heating can be obtained from the specific absorption rate (SAR), from temperature increase as function of time when the RF field is applied in the colloidal system. In this work, we studied iron oxide magnetic nanoparticles (IONPs), specifically Fe3O4 (magnetite), with diameters between 6-25 nm synthetized by high-temperature thermal decomposition of organometallic precursors. The crystal structure and morphology of these IONPs were determined by X-ray Diffraction (XRD) and Transmission Electron Microscopy (TEM). The magnetic properties were obtained by DC magnetic measurements using SQUID magnetometry. By controlling the size of these samples, we were able to compare (between the different sizes of nanoparticles) the SAR in magnetic hyperthermia experiments for frequencies between 90 kHz and 300 kHz and magnetic field amplitude up to 56 mT. The measured SAR value of the 17 nm MNP dispersed in paraffin presented an interesting value of 804 W/g in 103 kHz and 56 mT configuration that does not correspond to the linear response theory, where it was expected to achieve the maximum SAR value of 635 W/g. This sample presented a saturation magnetization of 80 emu/g and coercivity fields of 0.397 kOe at 2 K and 0.064 kOe at 300 K.

Induction hysteresis loop tracer with μ-emu sensitivity

Claudio Alejandro Gonzalez Fuentes[1], Christian Orellana[2], Maria Abellan[3], Gabriel Aguilar[2], Ricardo Henriquez[4]

[1]Universidad de Santiago de Chile (*Física*) , [2]Universidad Técnica Federico Santa María (*Física*) , [3]Universidad Técnica Federico Santa María, [4]Universidad Técnica Federico Santa María (*Physics*)

e-mail: claudio.gonzalez.f@usach.cl

Standard experimental tools for probing the magnetic moment of materials research include the superconducting quantum interference device (SQUID) and vibrating sample magnetometer (VSM).

A less common alternative is the use of an ***induction magnetometer*** or equivalently a ***magnetic flux-meters***, which can get magnetization directly by integration of Faraday''s law induction voltage.

Despite this alternative is by far more affordable than SQUID and VSM devices and intrinsically more versatile, its usage for the study of magnetic thin films is up to now, not possible, due to its smaller sensibility in the range of 10^{-4}emu.

In this work, we present a table-top, own design, very low-cost hysteresis loop (H-loop) tracer based on magnetic-flux quantification, suitable for the study of ferromagnetic thin films. Our device is capable to obtain H-loop curves of ultra-thin films of permalloy (NiFe), in a matter of minutes (Fig. 1). having a verified sensitivity limit in the order of $\sim$ 10$^-6$ emu.

In addition, our device is especially suited for the study of soft magnetic materials, being capable to detect changes in the coercive field as small as 0.1 Oe. The performance of our device was assessed by the study of the magnetic moment per unit area in NiFe ultra-thin films deposited on silicon dioxide substrates, where a native oxide layer on NiFe with a thickness equal to 1.6 $\pm$ 0.2 nm was determined.

Investigation of superconductivity which emerges fromRu intercalation in a Dirac semimetal of $ZrTe_2$ composition

e-mail: larissaishiikura@usp.br

Dichalcogenide materials are characterized by the chemical formula MX_2, which structure is defined by X-M-X type layers, that weakly interact with each other by Van der Waals type interaction [1]. The $ZrTe_2$ compound is a transition metal dichalcogenide which, according to the modern view of electronic structures, has a non-trivial topology and can be classified asa Dirac semimetal. The present study aims at the controlled intercalation of Ru between Te atoms in the $ZrTe_2$ compound with the purpose of obtaining a new topological superconducting material, since a relatively extensive range of atoms and molecules, when intercalated between the layers of these materials, is able to suppress the charge density wave transition, inducing superconductivity [2], two competitive phenomena to the Fermi surface, which, in general, coexist in this class of materials. The study was carried out by growing high-quality single crystals using the isothermal chemical vapor transport method [3], which were characterized by X-ray diffraction and energy dispersive spectroscopy, and the four-probe method was used for resistive characterization. So far, single crystals of nominal $Ru_{0.1}ZrTe_2$ composition have been synthesized and characterized, in which the phenomenon of multiband superconductivity was successfully identified, with critical temperature of 3.0 K. The occurrence of this behavior in this compound was associated with a possible hybridization between the p orbitals of Te and the d orbitals of Ru, which wouldbe responsible for originating a chemical pressure in the matrix.

Antibiotics are essential medicines for the prevention and treatment of bacterial infections in humans and animals. The presence of this antibiotic in the aquatic environment can cause toxic effects and potential development of resistant bacteria [1]. In this work, nickel ferrite (NiFe2O4) nanoparticles (NPs) were synthesized by coprecipitation, annealed at 623 K and characterized by X-ray diffractometry (XRD), Fourier transform infrared spectroscopy (FTIR), Mössbauer spectroscopy (ME), vibrating sample magnetometry (VSM), electrophoretic light scattering and gas adsorption. In addition, the application of NiFe2O4 NPs as an adsorbent for the antibiotic tetracycline (TCN) was investigated. The experimental data confirmed the formation of the partially inverse spinel phase of NiFe2O4 with crystallite sizes of 6 nm, superparamagnetic behavior, low saturation magnetization and coercivity, isoelectric point close to pH 7 and mesoporous structure. The non-linear equilibrium data better fit the Redlich-Peterson model, suggesting that the isotherm form approximates that of Freundlich. The kinetics non-linear fit indicated that the experimental data better fit the Elovich model. In addition, FTIR showed a shift from 1580 cm-1 to 1595 cm-1 in the absorption band v(C=O). This perturbation may be related to the formation of a hydrogen bond between the hydroxyl groups on the NiFe2O4 surface and the C=O group of the TCN keto-enol function.

In the present work, we investigate the achievement of logic operations on Y-shaped spin wave logic gates, composed of two input chains coupled to an output chain. We analytically calculated the transmission spectrum for a ferromagnetic and antiferromagnetic Y-shaped chains. We obtain the logical operations AND, OR and XOR, and demonstrate that the desired logical operation can be controlled by manipulating the phase difference between the incident waves. A study of the contrast ratio was also used to better characterize the efficiency of the logic gate.

In this work, we compare the magnetic and magnetocaloric properties of compounds with $Dy_{1-x}Tb_xAl_2$(where x = 0, 0.15, 0.35, and 0.4) modeled using a Hamiltonian that includes exchange interactions among Dy-Dy, Dy-Tb, and Tb-Tb ions, as well as the crystalline electric field and the Zeeman effects, with experimental results.To reproduce the experimentally observed ferromagnetic ordering and spin reorientation transition temperatures as the Tb concentration (x) varies [1], the exchange interactions within the rare earth sub-lattice were treated as free parameters and adjusted to match the experimental results.Our findings indicate that the heat capacity of polycrystalline materials in non-zero magnetic fields can be satisfactorily reproduced by averaging the main three field directions with respect to the crystallographic coordinate system. Moreover, we demonstrate a reasonably good agreement between the experimentally [1] determined and theoretically predicted magnetocaloric effects.

e-mail: adelia.vic@gmail.com

Since the discovery of graphene in 2004, this material has been widely studied due to large range of applications associated with its electronic structure, a band gap frequency inside the visible spectrum, high chemical stability, high thermic resistance, biocompatibility, high electrical conductivity and hardness. Others carbon base materials has been explored, among them the graphitic carbon nitride (g-C3N4) that presents various morphologies, likeporous nanosheets, nanorods, nanoflakes and nanotube. In particular, the combinations of g-C3N4 with magnetic materials to improve photocatalytic activity, pharmaceuticals nanocarriers action and hydrogen generation has been largely search, among the well-known and study magnetic materials used, are ferrite and magnetite (Fe3O4). Until this moment has not been find, any work that aims at the enhancement of magnetic properties on composites of g-C3N4/ Fe3O4. The present work uses urea synthesis to provide a most graphitic state to graphitic carbon nitride, which allows an easier incorporation of magnetite in to the material. The composites of (1-x) g-C3N4/ (x) Fe3O4 with x= 0,01; 0,05; 0,10; 0,20; 0,30; 0,40 has their structure analysed with DRX and MEV techniques and the magnetic properties were characterized with VSM magnetometer. The results show that the formation of Fe3O4 clusters induced a superparamagnetic behavior in samples that depend on synthesis route and the distribution of grains in g-C3N4 matrix.

Magnetic field driven superconductivity in Nb-Bi composites

Carlos Alberto Invernizzi Canhassi[1], Yakov Kopelevich[2]

[1]Universidade Estadual de Campinas (*ifgw*) , [2]Universidade Estadual de Campinas

e-mail: carloscanhassi@hotmail.com

We report the results of magnetoresistance and magnetization measurements performed on granular Nb-Bi composites prepared under different pressures (P) up to P = 2 GPa, where Nb is conventional s-wave superconductor (SC) and Bi is the elemental semimetal Bismuth. One of the characteristic physical properties of conventional superconductors is the suppression of superconductivity by applied magnetic field. However, the main result of the present work is the observation of superconductivity in Nb-Bi granular composites through the application of the external magnetic field. We discuss our finding within a framework of theoretical models for the negative intergranular Josephson coupling, as well as the possibility of emerging Majorana fermions at the Bi/Nb interfaces. Our recent observation of the pressure-induced ferromagnetism in Bismuth points out on the interrelation between the ferromagnetism and field-induced superconductivity in Nb-Bi.

Magnetic properties of superparamagnetic $Mn_{0.8}Zn_{0.2}Fe_{2-x}Ce_xO_4$ synthesized using the sol-gel auto- combustion route

e-mail: mattheus.torquato@gmail.com

Cubic ferrites are metal oxides with composition AB_2O_4, where A and B are divalent and trivalent cations, respectively, and one of the trivalent cations is the Fe^{3+} ion. There are two different sites in its crystal structure, tetrahedral sites, where the cations are surrounded by four oxygen ions, and octahedral sites, where the cations are bonded to six oxygen ions. The cation distribution among the tetrahedral and octahedral sites is partially responsible for the magnetic properties of a cubic ferrite. Recently, rare earths have been explored as cation substitute; the results suggest that introduction of small concentrations of them leads to a weaker magnetic response, which could be desirable for applications such as magnetic hyperthermia [1]. In this study, we investigated the influence of Ce^{3+}substitution on the magnetic properties of the manganese-zinc ferrite $Mn_{0.8}Zn_{0.2}Fe_{2-x}Ce_xO_4$ with x = 0; 0.015; 0.030; 0.050 and 0.100. The samples were synthesized by the sol-gel auto-combustion method and characterized by X-ray diffraction (XRD), Mössbauer spectroscopy (MS), Raman spectroscopy (RS), transmission electron microscopy (TEM), electron diffraction by selected area diffraction (SAD), and vibrating sample magnetometry (VSM). The XRD results show that the crystallite size are less than 8 nm for all samples and the cubic ferrite phase has obtained. The room temperature MS spectra show doublets that suggest superparamagnetic behavior and MS spectra at 5 K show two sextets, indicating the presence of Fe^{3+}in tetrahedral and octahedral sites. The TEM and SAD results confirm the small size and the crystal structure of the particles, respectively, and VSM results show a decrease in the saturation magnetization when cerium atoms are incorporated in the material.

Magnon heat-current approach for the spin Seebeckand spin Peltier effects based on the Boltzmann's theory

Samir Santos Costa[1], Luiz Carlos Sampaio[2]

[1]Universidade do Estado do Rio de Janeiro (*FCEE*) , [2]Centro Brasileiro de Pesquisas Físicas

e-mail: costa.samir@gmail.com

Spincaloritronics essentially deals with phenomena that exhibit a connection between spin and heat currents. In this field, two effects have been investigated (experimentally and theoretically) by several research groups: the spin Seebeck effect (SSE), and the spin Peltier effect (SPE). In SSE, a temperature gradient applied to a magnetic material (MM) gives rise to a spin current in it, which can be measured with the aid of a metallic layer (ML) due to the inverse spin Hall effect [1]. In contrast, the reciprocal effect, the SPE, a temperature variation at the interface of the MM/ML system can be verified when a charge current flows in the ML layer. As a consequence of the spin Hall effect, the charge current converts into a spin current, and the spin flux through the interface causes a temperature variation in this region [2].

In this work, a unified theoretical approach is proposed for both effects, which is based on Boltzmann''s theory in the relaxation time approximation. This allows the definition of the magnon spin and heat currents. The model is developed for an insulating ferromagnetic material. The treatment is carried out considering the magnonic heat current and its corresponding continuity equation. The connection between the spin and heat currents at the interface is performed by assuming that each magnon carries angular momentum and an average energy, the last defined from a occupation distribution close to equilibrium [3]. As a consequence, a unique dependence on the thickness of the magnetic layer is directly obtained for both effects. Finally, our calculations are compared with experimental data reported in the literature by other groups for the YIG/Pt.

The recent interest of the scientific community in magneto-optical interactions and interface effects has opened the possibility of a global understanding of characteristics not yet dazzled in materials. In this context, nanowires and films of magnetic materials have always been sources of research. Based on this interest, we studied both magneto-optical interactions and interface effects in ferromagnetic nanowires and antiferromagnetic thin films [1-3]. In the results involving nanowires, we observed that the intensity value obtained from the interactions provides information about their magneto-optical behavior, in addition to obtaining the quantitative value of these interactions, which are magnetizing and demagnetizing [1,2]. On the other hand, our experiments at paramagnetic/antiferromagnetic interfaces show the existence of a new magnetic effect detected by ferromagnetic resonance with and without applied electric current [3].

e-mail: gislaynealves@estudante.ufscar.br

Heterostructured multifunctional materials have been extensively studied due to their physical properties and potential in numerous applications. However, obtaining these materials is challenging. New synthesis protocols need to be developed to ensure adequate homogeneity between the constituent phases. Microwave-assisted hydrothermal synthesis offers advantages such as homogeneous composition, low temperatures, and shorter synthesis time compared to other methods. Therefore, this work aimed to prepare the 50(Na0.5Bi0.5)TiO3 - Ba0.06TiO3/50CoFe2O4 (NBT-BT6/CFO) magnetic system, using the microwave-assisted hydrothermal to achieve a particulate magnetic nanopowders with a consistent distribution of phases and reduced energy consumption during the synthesis process. The nanopowders were synthed in two stages: first, the NBT and BT phases were prepared at 200 °C for 2 hours, and successively the CFO phase was prepared at different temperatures (120-150 °C) and times (15 to 45 min) in the one pot. From the results of the morphological analysis by SEM and TEM and structural analysis (XRD), the formation of the NBT, BT, and CFO phases were observed on a nanometric scale and homogeneous distribution of the particles. In addition, the nanopowders presented a saturation magnetization of around 39.8 emu/g with a magnetic hysteresis that can be related to soft magnetic materials. Thus, one-pot microwave-assisted hydrothermal synthesis of multiphase nanoparticulate powders has potential to be used in the preparation of nanopowders with magnetic applications.

Molecularly imprinted magnetic polymer using semi-covalent chemical imprinting approach for application preconcentration of oxytetracycline and determination for HPLC-DAD.

Letícia Maria Effting[1], César Ricardo Teixeira Tarley[2]

[1]Universidade Estadual de Londrina (*Química*) , [2]Universidade Estadual de Londrina

e-mail: leticia.effting21@uel.br

Magnetic dispersive solid phase extraction employing magnetic molecularly imprinted polymers has been utilized due to the selective adsorption of the target by the polymer1. The present work had as objective to develop a new analytical method based on preconcentration of oxytetracycline (OTC) using a magnetic molecularly imprinted polymer (Fe3O4/SiO2/MIP). The innovative feature of this work relies upon semi-covalent synthesis, in which the template-monomer complex was synthesized by the reaction of the functional monomer 3-triethoxysilylpropyl isocyanate (ICPTES) via covalent bond with the OTC molecule. Removal of the OTC by chemical cleavage produced specific OTC recognition sites. The non imprinted polymer was synthesized by replacing the OTC-ICPTES complex for the (3-aminopropyl)triethoxysilane with the goal of obtaining the same functional groups of the magnetic-MIP. A specific superficial area of 216.0 m2g-1 was observed for Fe3O4/SiO2/MIP superior to Fe3O4/SiO2/NIP (103.6 m2g-1). From competitive adsorption studies it was observed that the Fe3O4/SiO2/MIP presented greater selectivity to OTC compared to the concomitants and comparison to Fe3O4/SiO2/NIP. The maximum adsorption capacity of Fe3O4/SiO2/MIP was 8.78 mg g-1. The result is considered satisfactory, especially due to the reduced extraction time (80 s). The method is based on the preconcentration of 40.0 mL of standard/sample (pH 4.0) vortex-assisted with 10 mg of Fe3O4/SiO2/MIP during 60 s. The elution was performed with 400 μL of oxalic acid 0.01 molL-1/acetonitrile (77.5/22.5 v/v). The method presented limit of quantification and detection of 0.26 and 0.89 μg L-1, respectively, and preconcentration factor of 90.44 times. The method was applied to determine OTC in water and milk samples with recovery resultsranging from 94.0-99.0%.

e-mail: wagner.macedo@posgrad.ufsc.br

Nd-Fe-B sintered magnets are experiencing significant growth in demand, mostly due to an increase in greener applications such as electric motors in transportation. Nd-Fe-B sintered magnets are almost exclusively produced via the traditional Powder Metallurgical Route, which includes a pressing step before the final sintering operation. However, the necessary fine-grained microstrostructure after sintering leads to the use of a very fine metallic powder, not ideal for pressing, due to the lack of flowability and consequently, density gradients in the green body. Such gradients cause undesired distortions in the sintered part, which must be corrected by machining operations and consequently generate large material losses. The highly oxidized swarf can not be directly reused, and value-added elements (rare earths - e.g. Nd, Pr, Dy) must be recycled by energy and chemical intensive processes, attenuating the benefits of the magnets for a greener economy. A promising process approach is presented in this work that makes use of fine alloy powder, produced by autogenous milling, which can be sintered to full density without the pressing stage (Press Less Process, or PLP [1]). In this work, the powder was fed into graphite and titanium molds in different amounts in order to vary the apparent density, followed by a special vibrating procedure and a pulsed magnetic field that was used to develop the crystalline texture. The suitably packed molds were then loaded into a tubular furnace for the sintering stage (sintering at 1050 ℃/1 hour followed by heat treatments at 900 ℃/1 hour and 600 ℃/1hour). The magnetic properties of the magnets obtained by the PLP process varied according to the filling density. After sintering, the magnets shown excellent shape retention, densities in the range of 6.9-7.4 g/cm3 and coercivities between 708-933 kA/m.

Novel synthesis and physical properties of $CoFe_2O_4$@$CoFe_2$ Core@Shell nanostructures

Marcos Santos Nunes[1], Lucas Marques da Silva[1], Marco A. Morales[1], José Humberto de Araújo[1]

[1]Universidade Federal do Rio Grande do Norte (*Department of Theoretical and Experimental Physics*)

e-mail: marcosantossn@gmail.com

In this work we present a study of $CoFe_2O_4$@$CoFe_2$ nanostructures of the core@shell type, which were synthesized by a new method without the use of special reagents or gases. First, we prepared small chitosan spheres with Co and Fe ions that were cross-linked ina solution with glutaraldehyde and NaOH. Second, the chitosan spheres were thermallytreated at high temperatures and in a vacuum, under a low pressure of 0.02 Torr, for 1h. The CO gas released from chitosan during the thermal treatment helped to reduce the $Fe^{3+}$and $Co^{2+}$to their zero valence state. Four samples were produced at temperaturesof 400, 500, 600 and 700 °C, and their structure, particle size, morphology and magneticproperties were studied. The X-ray difraction and Mössbauer spectroscopy showed thepresence of $CoFe_2O_4$and $CoFe_2$magnetic phases for samples prepared at 400 and 700 °C, respectively. For samples prepared at 500 and 600 °C we have obtained core@shell particles with crystallite sizes of 6.57-7.40 nm and 22.4-26.1 nm for $CoFe_2O_4$ and $CoFe_2$ phases, respectively. TEM images confrmed the presence of nanoparticles with core@shell confguration. Magnetic measurements showed that the $CoFe_2O_4$and $CoFe_2$phases, forthe sample treated at 600 °C, are coupled via exchange coupling, leading to a $(BH)_{max}$=0.67 MGOe. The estimate of the experimental thickness of the $CoFe_2$phase is 9.0 nm and is smaller than the critical size of 10.2 nm obtained by the Kneller-Hawig theory [1].

[1]Universidade Federal de Pernambuco (*DF*) , [2]Gleb Wataghin Physics Institute, University of Campinas, [3]Universidade Federal de Pernambuco (*Física*) , [4]Universidade Federal de Pernambuco (*Departamento de Física*) , [5]Universidade Federal de Pernambuco

e-mail: edycleyson.souza.116@ufrn.edu.br

The phenomenon of exchange bias (EB), also called exchange anisotropy, or unidirectional anisotropy, results from the interfacial magnetic interactions at the atomic contacts between ferromagnetic (FM) and antiferromagnetic (AF) materials. Discovered over six decades ago [1], this phenomenon has been widely investigated theoretically and experimentally by means of several techniques and has also found applications in magnetoelectronic and sensor devices [2-3]. In FM/AF thin film bilayers the most known manifestation of the EB is the shift of the hysteresis loop along the field axis by some value Heb that varies inversely with the thickness of the FM layer. Usually, the exchange bias direction is opposite to the direction of the magnetic field applied during the sample growth, and is called negative EB. The reverse situation in which the hysteresis loop shifts in the direction of the field applied in the sample growth, called positive EB, was first observed in bilayers of Fe/FeF2 and is usually associated with an antiferromagnetic interfacial coupling at the FM/AF interface. We report an experimental study of the unidirectional anisotropy in bilayers made of the important ferrimagnetic insulator yttrium iron garnet (YIG) and the room temperature antiferromagnet IrMn. Measurements of the magnetization hysteresis loop in a wide temperature range and ferromagnetic resonance at room temperature revealed an unconventional positive exchange bias (EB). The presence of the positive EB is attributed to an antiferromagnetic coupling between the spins of the two layers at the interface.

Reducing the Use of Costly Heavy Rare-Earth Elementsin Nd-Pr-Fe-B Magnets

Wagner Costa Macedo[1], Paulo Antônio Pereira Wendhausen[1], Leonardo Fernandes Antunes[1], Douglas A. P. Silva[1], Luis Torres Quispe[1]

[1]Universidade Federal de Santa Catarina (*Department of Mechanical Engineering*)

e-mail: wagner.macedo@posgrad.ufsc.br

The demand for magnets for new high-frequency applications that must withstand high temperatures is growing, especially in motors for electric vehicles. Conventionally, this has been circumvented by partially substituting Nd for Heavy Rare-Earth Elements (HREE) such as Dy or Tb. This however increases raw-materials cost to the magnets production, since HREE are more scarce than Nd or Pr. Nevertheless, a new approach proposed by Hirota et al. [1] has shown that this element substitution does not necessarily have to be accomplished uniformly throughout the microstructure. Moreover if the additive (Dy) is cleverly located at the grain boundaries, an analogous effect is achieved to that when Dy is homogeneously distributed. One interesting method to accomplish that is by the so-called Grain Boundary Diffusion (GBD) which consists of a method of incorporating Dy through the grain boundaries of previously sintered magnets, under high temperatures, keeping the core of most grains intact. The main challenge of this technique is to obtain a shell-structure microstructure where the generation of high coercivity is related to a Dy-rich area on the grain periphery of the main phase ($Nd_2Fe_{14}B$), and a Nd-rich phase (Nd-Rich) on the grain boundaries [2]. In this work we report the feasibility of this method by using a Dy-rich eutectic alloy, which was previously embrittled to facilitate its comminution. The powdered alloy was then added to the surface of green compacts, or blended in the base alloy powder, in order to promote Dy diffusion through the grain boundaries simultaneously to the sintering process. The results show that the magnets in which Dy was added by the GBD method were able to achieve similar properties in the final magnet with 50% less addition of the HREE.

Spin and charge DFT simulation on $CaFeO_3$ modified by oxygen vacancy

Sergio Ricardo de Lazaro[1], Elson Longo[2,3]

[1]Universidade Estadual de Ponta Grossa (*Chemistry*) , [2]Univerdade Federal de São Carlos,
[3]Universidade Federal de São Carlos

e-mail: srlazaro@uepg.br

The presence of oxygen vacancies in semiconductor oxides is not a novelty. Oxygen vacancies are n-type semiconductors, the Fermi''s energy modulates optical and electrical properties. For another hand, the Electron Paramagnetic Resonance (EPR) reported oxygen vacancy and magnetism for $CaTiO_3$material because of unpaired electrons promoting a charge transfer and photoluminescence effect [1].

Spin moments analysis in $CaFeO_3$indicates a residual up spin moment on the O atoms connecting the Fe atoms with 3.755 mB each. After oxygen vacancy, changes to the AFM order and 4.221 mB and -4.221 mB, respectively. Mössbauer technique identified magnetic changes on iron sites for $CaFeO_3$and $Ca_2Fe_2O_5$materials corroborating with model [2]. The introduction of one electron induces a FeM magnetic state. In contrast, O atoms have anisotropic spin moments distribution intensifying the magnetism on the Fe atom. The

Structural and magnetic properties of $CoFe_2O_4$ nanostructures produced by pulsed laser deposition

In this work, we studied the magnetic and structural properties of cobalt ferrite nanostructures produced by pulsed laser deposition. We focus our investigation on spatial arrangements of nanoparticles with different degrees of porosity. The nanostructures were studied under different pressures in the deposition chamber: vacuum (10^{-6}Torr) and high pressures (0.1, 0.25, 0.5, and 1.0 Torr) of O_2. Scanning electron microscopy showed the growth of a thin film for deposition under vacuum and an arrangement of nanoparticles for the other pressures. It was observed that the distance and size of the nanoparticle clusters decrease with increasing deposition pressure, and after applying a pressure of 1.0 Torr, we observed a very porous system of nanoparticles. The high-resolution transmission electron microscopy analysis showed that the average size of the deposited nanoparticles is independent of the value of the deposition pressure. The magnetic results showed that the magnetic properties of nanoparticles are strongly influenced by pressure. The effects of magnetic interaction between nanoparticles generate, from a spin glass-like behavior for low deposition pressure to a behavior close to the expected for superparamagnetic systems for nanoparticles deposited under high pressure. Despite the pressure change in the deposition of the different cobalt ferrite samples, the electron diffraction results from the selected area provided the same crystallographic structure. The structural and morphological characterizations of the nanostructures deposited by PLD carried out in this work reveal important and unprecedented details of the nanostructures obtained using the PLD technique. In addition, we carried out a study of the capacitance of the cobalt ferrite nanostructures produced to check the potential of these nanostructures to be used in applications as supercapacitors.

Structural, magnetic and superconducting properties of NbC_x Nanoparticles produced by laser ablation in liquid

Fernando Fabris[1], Ali Francisco Garcia Flores[2], Ricardo Rodrigues Urbano[2], Carlos Rettori[3]

[1]Universidade Estadual de Campinas (*Instituto de Física "Gleb Wataghin"*) , [2]Universidade Estadual de Campinas, [3]Universidade Estadual de Campinas (*Física*)

e-mail: fernandofbris@gmail.com

Niobium carbide (NbC_x) is a highly promising material for superconducting applications due to its critical temperature ($T_c$of 8-12 K) slightly above that of Nb and high critical magnetic field (H_{c2}that can be bigger than 4 T).[1] Reducing the of this material leads to significant changes in the superconducting behavior, such as enhancing the critical field and/or the superconducting temperature.[2] Hence, In this study, NbC_xnanoparticles were produced using laser ablation in acetone, with varying lens-target distances and centrifugation velocities to control the particle . X-ray diffraction analyses revealed the presence of cubic NbC_xphase in all samples. Electron microscopy images showed spherical particles ranging in from few nanometers to hundreds of nanometers for all samples. Room temperature magnetization curves exhibited magnetic loops for all samples with saturation magnetization around tens of milli emu/g. At 2K, in addition to the magnetic component, a typical superconducting loop was observed for larger particles. A $T_C$of around 10 K was observed for all sample however, the diamagnetism below $T_C$decreased with particle , and the magnetic phase tended to dominate. The coexistence of superconductivity and magnetism in nanoparticles has garnered significant research interest in recent years, and we will discuss it in this work for NbC_xnanoparticles. Nanoparticles possess unique properties that differ from their bulk counterparts due to their large surface/volume ratio, and the interplay between superconductivity and magnetism in these systems can lead to find new matter properties and improve our understanding of the superconducting phenomenon.

Fe_3O_4nanocrystals (NC) can be used as patterns for fundamental studies of magnetic properties on the nanoscale because of two main characteristics: i) Fe_3O_4presents magnetocrystalline anisotropy being its direction of easy magnetization, thus cubic and spherical NC must have different magnetic behavior ii) the critical diameter of $Fe_3O_4$is around 25 nm, below this the NC is a magnetic monodomain. DPC-STEM could be a powerful tool to investigate magnetic phenomena because it allows obtaining information about interactions between electrons beam and different local magnetic orientations.[1] However, it should be noted that DPC is not trivial, because the TEM lenses are electromagnets and some TEM components are ferromagnetic material, thus is necessary to ensure that the magnetic field (MF) arising from these components does not affect the analyses.[2] Here, we aim to investigate how an external MF affects the formation of self-assembly of Fe_3O_4NC, taking into account the NC shape as well as to evaluate interparticle magnetic coupling at room and low temperatures (~196 °C) by DPC-STEM. Both spherical and cubic monodisperse 10 nm NC were obtained, and initial results of DPC-STEM of self-assembly NC on the TEM grid. STEM conditions are being improved. The next steps are to obtain the assembly of NC in thin films with and without the external MF.[3] FC-ZFC measurements also will be performed for corroborates DPC-STEM data and help in phenomenological interpretation.

Study of the Magnetocaloric effect on frustrated triangular trimers

Julia Bastos Lyra Alves[1], Maria Socorro Seixas Pereira[1], Marcelo Leite Lyra[1]

[1]Universidade Federal de Alagoas (*Instituto de Física*)

e-mail: jbastoslyra20@gmail.com

We study the thermodynamic features of frustrated magnetic trimers that are relevant to evaluate the capacity of magnetic refrigerarion. Exact expressions for the entropy change and magnetocaloric refrigeration rate are obtained considering both Ising and Heisemberg antiferromagnetic couplings between 1/2-spins. We show that magnetic frustration leads to an improved magnetocaloric refrigeration rate at low magnetic fields and temperatures. Further, a second region of enhanced refrigeration rate appears near the critical field separating frustrated and saturated groundstates. Both direct and inverse magnetocaloric effect are observed in the vicinity of his critical field. We also discuss on the possible role played by quantum fluctuations acting together with magnetic frustation to enhance the magnetic refrigeration capacity.

Superconductivity and charge density waves in transition metal chalcogenides NbS_3 and S-doped $ZrTe_2$

Fabio Santos Alves Abud[1], João Pedro de Almeida Lopes[1], Leandro Rodrigues de Faria[1], Antonio Jefferson da Silva Machado[1]

[1]Escola de Engenharia de Lorena da Univerdade de São Paulo (*Departamento de Engenhariade Materiais*)

e-mail: fabio.abud@usp.br

Transition metal chalcogenides offer a wealthy playground to study the quantum effects related to low-dimensional systems. This family of Van der-Walls materials includes both the dichalcogenides (TMD) $MX_2$and trichalcogenides MX_3(TMT) variants (M = transition metal and X = Se, S, or Te). While the TMDs are known to feature quasi-2D properties, the TMTs materials are suggested to possess quasi-1D quantum properties, with the potential emergence of strongly correlated phenomena and topological effects, otherwise unattainable in other systems [1]. Despite being slightly distinct, the structural features of both TMD and TMT lead to charge density wave (CDW) ordering and highly anisotropic physical properties; in some cases, there is also coexistence between superconductivity and CDW in the TMD and TMTs [2]. In order to probe this coexistence, we have grown single crystals of intercalated TMT $NbS_3$and TMD S-doped $ZrTe_{2-x}S_x$using the isothermal chemical vapour transport, a technique recently developed by our group [3]. The physical and structural characterizations conducted in our crystals include X-ray diffraction, energy-dispersive spectroscopy, temperature and magnetic field dependent electrical resistance $\rho(T,H)$ and magnetization $M(T,H)$. Our results will be discussed focusing on the emergenceof superconductivity due to doping, intercalation, or off-stoichometry mechanisms, which may also lead to the suppresion of the CDW ordering.

e-mail: lucas7900@gmail.com

We present measurements of structural, electrical, and thermoelectric potential on high-quality single crystals of ZrTe1.8 grown from isothermal chemical vapor transport. Our results indicate that despite being Te-deficient and sharing the same structure as the non-superconducting ZrTe2, ZrTe1.8 exhibits superconductivity below 3.2 K. The temperature dependence of the upper critical field (Hc2) deviates from the behavior expected in conventional single-band superconductors and is best described by an electron-phonon two-gap superconducting model with strong intraband coupling. Seebeck potential measurements of the ZrTe1.8 crystals suggest that the charge carriers are predominantly negative, consistent with ab initio calculations. Moreover, our DFT-based first-principles calculations reveal that the inclusion of Te vacancies in ZrTe2 unexpectedly leads to the formation of localized Zr-d bands and a density of states peaks at the Fermi level, possibly promoting electronic instabilities at the Fermi level and increasing the critical temperature according to the standard BCS theory. These findings suggest that Te deficiency can fine-tune the electronic structure to support superconductivity in TMDs and highlight the role of defects in promoting the stability of the superconducting ground state.

Superconductivity in Terbium intercalated $ZrTe_2$

Antonio Jefferson da Silva Machado[1], Leandro Rodrigues de Faria[1], Lucas Eduardo Correa[2], Larissa Miki Ishikura[1], Milton Torikachvili[3]

[1]Escola de Engenharia de Lorena da Univerdade de São Paulo (*Departamento de Materiais*), [2]Centro Nacional de Pesquisa em Energia e Materiais (*LNLS*), [3]San Diego State University (*Department of Physics*)

e-mail: ajefferson@usp.br

$ZrTe_2$ is a part of the transition metal dichalcogenide family, comprised of two-dimensional materials where van der Waals forces create a layered structure in which foreign species may be intercalated between chalcogenide layers. $ZrTe_2$ in particular, may be regarded as a Dirac semimetal where multi-gap superconductivity has been previously reported for Cu (T_c= 9.0 K), Cr (T_c= 5.4 K) and Ni (T_c= 4.0 K) intercalated specimens, as well as for Tellurium deficient samples (Tc = 3.2 K). Due to the possible coexistence between superconductivity and non-trivial topology, $ZrTe_2$ is a good candidate for probing of the interplay between different emerging quantum states, and the intercalation of atoms with incomplete *f* electron shells may be a good path to unveil the intricacies of this system and gain insight on the type of pairing mechanisms that induce superconductivity in this compound. In this work we prepared single crystals of Terbium intercalated $ZrTe_2$ single crystals, and we show superconductivity is developed with T_c in the vicinities of 5.0 K. The single crystals are characterized by means of X-ray diffractometry and Energy Dispersive Spectroscopy, and its superconducting properties are characterized by means of DC electrical resistivity and magnetization measurements.

This study reports the successful preparation, characterization with temporal analysis of an organic magnetic fluid using superparamagnetic nanoparticles coated in essential oil of Copaifera Officialis L.. Therefore, the Fe_3O_4nanoparticles will be synthed by the coprecipitation method by hydrolysis in an alkaline solution. Ferrofluid will be prepared by dispersing magnetic nanoparticles, at five different concentrations, in the in natura oil. For the samples characterization measurements were taken of: UV-vis, FTIR, NIR spectrophotometry, XRD and Magnetic Susceptibility, the temporal analysis was recorded periodically, observing the possible stability of the samples. The Molar Susceptibility and XRD data show that SPIONs have an average diameter of 21 nm and are highly susceptibleto magnetic fields. The analysis by spectrophotometry in UV-Vis and NIR indicate that the magnetic fluid has the properties associated with Amazon natural oil. the samples showed good stability, the data indicate that the concentrations of 13% and 16% are the most suitable for the synthesis of magnetic fluids based on the vegetable oil of Copaifera Officialis L. [1,2].

Rare earth-nickelates are a class of electronically correlated oxides, where their physical properties are directly related to their crystalline structure. These compounds crystallize in the rhombohedral or orthorhombic distorted perovskite structure, where structural distortion or chemical substitution directly influences their physical properties [1]. LaNiO3 crystallizes in rhombohedral-distorted perovskite structure and has a metallic behavior from2 to 300K. The characteristics of high electrical conductivity and high thermal stability observed experimentally for LaNiO3 nanoparticles have motivated the study of its field emission properties. In particular, the use of conductive nanotubes or nanowires can also function as localized sources of electrons. In this context, this work produced LaNiO3 nanowires by electrospinning to evaluate their transport and field emission properties. For this, the wires were produced from a La-Ni precursor solution, with a viscosity of ~1000cP. Electrospinning was performed and they are being characterized by X-ray diffraction, scanning electron microscopy (SEM) and electrical transport measurements. Preliminary characterizations revealed that these compounds crystallized in the rhombohedral-distorted perovskite (R-3C) LaNiO3 phase, without the presence of additional phases. SEM images showed that the samples are shaped like nanowires with lengths of several micrometers (5 to 7μm) and an average diameter of around 150nm. Transport properties are currently being evaluated.

e-mail: lucimara.ramires@uel.br

The use of magnetic nanomaterials for ion preconcentration has received significant attention in recent years due to the absence of filtration and/or centrifugation steps in extraction procedures. However, due to the high aggregation power and lack of selectivity of these magnetic cores, the modification of their surface with ionically imprinted magnetic polymers with restricted access (IIPs-RAM) has been highlighted for this purpose[1]. Thus, an IIP-HEMA-RAM was synthed using acrylamide and allylthiourea as functional monomers in the presence of BSA and HEMA as hydrophilic co-monomers. To evaluate the effect of chemical imprinting and exclusion of macromolecules, control materials, such as: unprinted and without restricted access, were also synthed. All materials were characterized by ATR-FTIR, SEM, MET, BET, DRX and TG to prove the formation of polymers and their structural and morphological characteristics. Optimizing factors that affect MSPE, such as pH, preconcentration and elution time, adsorbent mass, and sample volume, will be optimized univariately. From the ATR-FTIR spectra, it was possible to prove the magnetism of the material due to the presence of the band at 540 cm^{-1}, as well as the formation of a core-shell attributed to the band at 1100 cm^{-1}, characteristic of the Si-O bond and the band at 1641 cm^{-1}attributed to vinylic groups in the polymeric matrix. From the pH and zero charge point studies carried out for the IIP-HEMA-BSA material, more significant adsorption was observed at pH 6.0, proving that adsorption of the Pb2+ ion in the material occurs through interaction with acrylamide and allylthiourea monomers. Studies of selectivity, interferents, adsorption kinetics, and isotherms, as well as the application of the method in food samples, will be carried out.

SYNTHESIS OF BARIUM HEXAFERRITE PARTICLES PREPARED BY SOL-GEL COMBUSTION METHOD

Kerolaine de Jesus Tavares[1], Alysson Martins Almeida Silva[1]

[1]Universidade de Brasília (*Department of Mechanical Engineering*) *e-mail: tavareskerolaine@gmail.com*

Magnetic materials have always attracted human attention for being convenient in several applications of electronic devices such as permanent magnets and recently in treatments for diseases such as cancer and also for the release of drugs that can be conducted and limited in a given location by means of magnetic field. In this context, this work consists of the synthesis of barium hexaferrite particles ($BaFe_{12}O_{19}$) that were obtained through the sol-gel combustion method [1], employing as precursors barium nitrate and hydrated iron nitrate nona, besides that, citric acid and ammonium hydroxide were added to the solution. Phase formation was investigated by thermogravimetric analysis (TGA), X-ray diffraction (XRD) and scanning electron microscopy (SEM). The results reveal that the formation of the single-phase powder occurs with increasing temperature.

Theoretical DFT/HSE06 study of crystalline and electronic structure of X0.125Mg0.875B2 materials (X = Nb, Ni, Fe)

Guilherme Bonifácio Rosa[1], Sergio Ricardo de Lazaro[2], Luis Henrique da Silveira Lacerda[3]

[1]Universidade Estadual de Ponta Grossa (*DEQUIM*) , [2]Universidade Estadual de Ponta Grossa (*Chemistry*) , [3]Universidade Federal de Santa Catarina

e-mail: gbonifacioros@gmail.com

MgB2 material is widely applied in superconductors studies and generation of electronic devices, . The modification of these material is reported in literature with transitions metals in Mg site. Fabrication of superconductors wires of low-cost with MgB2 materials is reported as a promissory option to application in electronic devices and in magnetic resonance devices. With hexagonal P6/mmm space group, these material presents a versatile structure to modifications with transitions metals in Mg site [1].

The computational simulations in work were performed on DFT/HSE06 level in software CRYSTAL17, and VESTA viewer. The Mg, B, Ni, Fe and Nb atoms were described by 8-511G, m-6-311G(d), TZVP, s8411p6411d441 and 986-31(631d)G Gaussians basis sets respectively. The Mg0.875X0.125B2 (X=Nb, Fe and Ni) material was simulated in a 2x2x2 supercell in Mg site. The electronic profile based on the Electronic Band Structure (EBS) and Density of States (DOS).

Quantum simulations of MgB2 material compared with cell parameters a = b = 3.073 Å andc= 3.553 Å reported in literature [2], presents a good crystalline structure. Ni, Fe and Nbdoping presents low distortions in a and b parameter. The considerable distortion is the effect of Nb, Ni and Fe doping is the contraction in parameter c, denoting an approximationof layers. In EBS analysis is observed the effect of magnetic cation in structure in Fe and Nidoped material is that the paired electrons in beta channel forms the Dirac Cone in symmetry point A, while in Nb the Dirac Cone is observed in alpha and beta channel in Γand A point. In Fe and Ni doped materials, the profile of Dirac Cone is more defined and theintersection of Bands is most clear.

High entropy alloys are a group of advanced materials composed of five or more metallic elements mixed in roughly equal proportions. The concept behind HEAs is that by combining multiple elements in equal proportions, it is possible to create materials with high entropy or disorder, which can lead to improved mechanical, thermal, and electrical properties [1].

In this work, we report theoretical calculations of thermal and magnetic quantities such as magnetization and heat capacity, as well as magnetocaloric potentials (isothermal magnetic entropy (ΔS_T) and adiabatic temperature (ΔT_{ad}) changes) in the ferromagnetic high entropy alloy $Gd_{0.2}Tb_{0.2}Dy_{0.2}Ho_{0.2}Er_{0.2}Al_2$using a microscopic model. The model hamiltonian includes contributions from the Zeeman effect, crystalline electrical field anisotropy, and exchange interactions among the five different rare earth sublattices (Gd-Gd, Gd-Tb, Gd-Dy, etc.). Most of these were found by considering previous studies on pseudobinary compounds such as $Gd_{1-x}Dy_xAl_2$[1], $Gd_{1-x}Tb_xAl_2$[2], $Er_xTb_{1-x}Al_2$[3], $Ho_{1-x}Dy_xAl_2$[4], etc.

Experimental data [5] show that the Curie temperature is approximately the average of the individual components RAl2 (R = Gd, Tb, Dy, Ho, and Er). The theoretical results are in agreement with the available experimental data [5].

The magnetocaloric effect (MCE) - variation of the temperature of a magnetic material under the variation of the external magnetic field can be characterized by the variation of the cooling capacity (RC) and the magnetic entropy. We observe in general that the RC of an amorphous alloy is greater than its equivalent in the crystalline phase. Furthermore, structural disorder minimizes hysteresis losses, but the existence of local random anisotropy due to structural disorder can lead to more complex magnetic structures. Some consequences, for example, are the reduction of spontaneous magnetization and the reduction of the magnetic ordering temperature. In this work, we will investigate the magnetic and magnetocaloric properties of the amorphous alloys formed by the Gd54Fe36B10-xSix series. From an experimental point of view, these systems have been reported to have high values for refrigerant capacity and interesting magnetocaloric properties associated with ferrimagnetic ordering. We propose a theoretical model described by two coupled magnetic sub-lattices of localized spins in the presence of an applied magnetic field based on the Handrich approximation to study these systems. By means of this model, we calculate the magnetization and the isothermal entropy change as functions of the temperature under the change of the applied magnetic field. We will try to understand the role of the replacement of B by Si and the influence on magnetic entropy and the magnetocaloric effect of these systems. Furthermore, the study is important to understand the physical mechanisms involved in the ferrimagnetic transitions of amorphous alloys.

Thermoelectric response of Co-rich flexible ribbons

e-mail: marciocorrea@fisica.ufrn.br

$Fe_3Co_{67}Cr_3Si_{15}B_{12}$ribbons with a high degree of flexibility and excellent corrosion stability were produced by the rapid quenching technique. Their structural, magnetic, and thermomagnetic (Anomalous Nernst Effect) properties were studied both in an as-quenched (NR) state and after stress annealing during 1 h at the temperature of 350 ◦C and a specific load of 230 MPa (AR). X-ray diffraction was used to verify the structural characteristics of our ribbons. Static magnetic properties were explored by inductive technique and vibrating sample magnetometry. The thermomagnetic curves investigated through the Anomalous Nernst Effect are consistent with the obtained magnetization results, presenting a linear response in the thermomagnetic signal, an interesting feature for sensor applications. Additionally, Anomalous Nernst Effect coefficient S_{ANE}values of 2.66 μV/K and 1.93 μV/K were estimated for the as-quenched and annealed ribbons, respectively. The interplay of the low magnetostrictive properties, soft magnetic behavior, linearity of the thermomagnetic response, and flexibility of these ribbons place them as promising systems to probe curved surfaces and propose multifunctional devices, including magnetic field-specialized sensors.

GnP-doped Al_2O_3flexible tapes were produced through Tape Casting technique and used as substrates to produce Co_2FeAl/GnP-doped Al_2O_3heterostructures. The Co_2FeAl layers were grown using Magnetron Sputtering with a thickness of 30 nm. The integration of Tape Casting and Magnetron sputtering techniques allowed us to explore the thermomagnetic properties of the heterostructure through the Anomalous Nernst Effect. The structural and morphological properties of the substrates and the magnetization curves support the thermomagnetic results. The CoFeAl ferromagnetic films presented isotropic magnetic behavior, which was reflected in the thermomagnetic curves through the stability of the curve’s shape irrespective of the thermal gradient and angle of the external magnetic field used during the measurements. Our findings open new possibilities to produce flexible heterostructures with multifunctional properties, where the versatilities of the Tape casting and magnetron sputtering techniques bring new routes to build nanostructured materials.

Single-Molecule Magnets (SMMs) are at the forefront of the next generation of molecular-based electronics.[1] As their state-of-the-art is mainly based on heavy lanthanide ions, examples of light lanthanide-based complexes e.g., Nd^{III}, fall far behind due to the strong contribution of quantum-tunnelling of magnetisation (QTM).[2] Besides the slow relaxation of magnetisation, the luminescence of multifunctional SMMs can be used as a tool for ***in situ***temperature measurements through luminescence thermometry.[3] To help understand how the magnetic and luminescent features of Nd^{III}-based SMMs can be enhanced by structural modifications, herein, two dinuclear complexes, $[Nd_2(valdien)_2(X)_2]$ (X = $acac^-$ {1-Nd_2} or NO_3^- {2-Nd2}) (H_2valdien = N^1,N^3-bis(3-methoxysalicylidene)diethylenetriamine, $acac^-$= acetylacetonate), are presented. The complexes display field-induced slow relaxation of magnetisation, but for {2-Nd_2}, QTM has a lower contribution because the longer Nd^{III}-$O_{terminal}$bond distances induce a weaker equatorial crystal field component. Taking advantage of the Nd^{III}near-infrared emission, the systems were used to develop temperature probes displaying maximum thermal sensitivity of 0.52% K^{-1}at 40 K {2-Nd_2}. Therefore, this approach can enable mapping strategies to boost the luminescent and magnetic performance of similar multifunctional SMMs.

e-mail: Kacioreinaldo@gmail.com

Although heavy metal materials, due to their large spin-orbit interaction, would be expected to act as an efficient converter of spin current to charge current, Bismuth does not obey this rule. Heterostructures of yttriumiron garnet (YIG)/Bi are investigated by means of the spin pumping technique and the results show that Bi exhibits negligible spin-charge conversion. In addition to not converting spin to charge, Bi exhibits an exotic spin relaxation mechanism, which is driven by its large diamagnetic response. By considering a nonlinear stochastic model of diffusing spin particles, the results show that the Bi layer acts as a binary classifier device that categorizes the pumped spins into relaxed spins and those that flow upwards and eventually reach the toplayer of Pt. This shows that the investigation reported here opens different perspectives involving fundamental aspects in the fields of machine learning and condensed matter physics.

UNVEILING THE POLAR PROPERTIES ON BARIUM BISMUTHATE PEROVSKITE THIN FILMS WITH DISTINCT Ba/Bi RATIO

Alexandre Zirpoli Simoes[1], Gohnny Acero[1], Henrique Moreno[2], Miguel Angel Ramírez Gil[2]

[1]Universidade Estadual Paulista (*MATERIAIS E TECNOLOGIA*) , [2]Universidade Estadual Paulista

e-mail: zirpoli.simoes@unesp.br

In this work, we investigate the domain structure of Ba(1-x)BixO3 (x=0.2, 0.5, 0.7) synthesized via chemical solution deposition (CSD) method. The samples were named as BBO37, BBO55 and BBO82 according to distinct Ba/Bi ratio. The electrical response of the as-prepared BBO thin films was explained based on its (micro)structure, using a combination of Transmission Electron Microscopy (TEM), and X-ray diffraction (XRD). The piezo-ferroelectric coupled behavior, observed for BBO, was demonstrated, and elucidated in terms of point defects (e.g., oxygen vacancies and cation defects). All the films crystallizein a rhombohedral BaBiO3 structure with a R-3R space group without any deleterious secondary phase. TEM micrograph images indicate that the Bi content significantly influence grain morphology. Additionally, the hysteretic strain, dielectric, ferroelectric, and piezoelectric properties of BaBiO3 thin films are strongly dependent on the electronic structure. Hence, the electrical response of BaBiO3-based ceramics is determined by the presence of point defects (e.g., oxygen and bismuth vacancies) as well as grain morphology, which can be controlled by stoichiometric changes (Ba/Bi ratio). Sample BBO55 showed a distinguished preferred orientation along the (341) plane with a low associated coercive field (63.55 kV/cm), free of imprint and with no polarizations gap compared to samples BBO37 and BBO82. Sample BBO55 presented the highest piezoelectric (d33-eff≈ 45.7 pm/V) and ferroelectric (Pr≈13.67 µC/cm2) responses at room temperature. This behavior can be ascribed to a highly textured film, which generates less strain throughout the crystal lattice facilitating the polarization switching mechanism and improving piezo/ferroelectricity.

YIG films produced by the metalorganic decomposition method (MOD) lithographed by focused ion beam (FIB)for the study of spintronic phenomena

Lilian Kássia Cavalcante da Silva de Assis[1], José Elias Abrão Neto[2], Eduardo Padrón Hernández[1]

[1]Universidade Federal de Pernambuco (*Departamento de Física*) , [2]Universidade Federal de Pernambuco (*Física*)

e-mail: lilian.assis@ufpe.br

Yttrium iron garnet films - YIG (Y3Fe5012) have been widely used in the study of spintronic phenomena, induced by spin waves. Since silicon is highly compatible with microelectronic technologies, the continuous search for optimizing the process for obtaining these films has become a reality. This, thanks to the existing structural incompatibility between this substrate and the YIG. The manufacture of these films by chemical methods and, in particular, on silicon substrate, is still a great challenge. For this reason, large studies presented in the literature use conventional methods for the production of YIG films for these purposes. This work, in turn, aims to present quality YIG films in terms of morphology, as well as structural and magnetic properties, for studies of spintronic phenomena. The films were produced from the metalorganic decomposition method (MOD), being deposited by spin coating. The films were annealed at 850°C and characterized by XRD, SEM, Raman and FMR. The films showed a single-phase YIG structure, with a line width of 93 Oe in the ferromagnetic resonance (FMR) spectrum. Arrangements of hollow and non-hollow nanopillars were lithographed using the focused ion beam - FIB, becoming a perspective for spintronics studies.

Activation of alkane C-H bonds by Mn porphyrin-based catalysts immobilized onto SiO_2, SBA-15, and HMS materials as cytochrome P450 models

Isaque Augusto Aragão Feitosa[1], Victor Hugo Araujo Pinto[1], Shirley Nakagaki[2], Júlio Santos Rebouças[1]

[1]Universidade Federal da Paraíba (*Química*) , [2]Universidade Federal do Paraná (*Química*)

e-mail: iaaf@academico.ufpb.br

Cytochromes P450 are heme-containing monooxygenase enzymes that carry out the activation and selective oxygenation of inert C-H bonds of alkanes under mild biological conditions[1]. P450-like catalysts based on Mn-porphyrins (MnP) heterogenized onto silicas are actively sought after as biomimetic models[1,2]. In these systems the MnP mimics thereactivity of the heme group whereas the silica support models some of the protein roles. Hereon we describe the heterogenization of two structurally related MnPs onto ordinary chromatographic amorphous silica gel (SiO_2) and mesoporous silicas SBA-15 and HMS: Mn(III) *N*-methylpyridinium-2-ylporphyrin (MnP2) was electrostatically supported on non-modified silicas, whereas Mn(III) 2-*N*-pyridylporphyrin (MnP1) was covalently immobilized onto chloropropyl-functionalized silicas. All six materials were investigated as P450 models for cyclohexane (Cy-H) oxidation by iodosylbenzene. The SiO_2-Cl/MnP1 material was the most robust, efficient and selective (~60%) for Cy-H oxidation, with total yield of 89%. Recycling studies showed that the SBA-15- and HMS-based materials were somewhat more susceptible to oxidative degradation of MnP. Amorphous silica materials (SiO_2-Cl/MnP1 and SiO_2/MnP2) maintained a high overall yield, with some loss in efficiency on the 3rd cycle of use. Cyclohexanol selectivity was little affected by catalyst recycling. In this work, we show a comparison of the catalytic efficiency of the materials and the role of the silica support onto catalyst reactivity and P450 modeling.

A new biopolymer obtained from glycerol and maleic anhydride using a polythiol as a crosslinking agent by photopolymerization

Gabriel Iago dos Santos[1], Caroline Gaglieri[1], Rafael Turra Alarcon[2], Gilbert Bannach[1]

[1]Universidade Estadual Paulista (*Química*) , [2]Universidade de São Paulo

e-mail: gabriel.i.santos@unesp.br

Nowadays, glycerol and maleic anhydride emerge as proponents of green inputs for the production of biopolymeric materials [1]. In addition, the use of polyols for the production of biopolymers with properties similar to those from non-renewable sources has been producing materials of high technological interest [2]. Thus, in the present work, it was performed the synthesis of a pre-polymer using glycerol and maleic anhydride, which subsequently was mixed with the polythiol pentaerythritol tetrakis(3-mercapto propionate). The final polymer was obtained by photopolymerization (using the photoinitiator 2,2-dimethoxy-2-phenylacetophenone and UV light). The mid-infrared absorption spectroscopy (MIR) analysis suggested the formation of an ester (from pre-polymer) and the consumption of double bonds of the alkenes, suggesting the occurrence of the thiol-ene reaction. The final material presented luminescent properties, showing a great potential to use as sensors.

Antistatic and antimicrobial packaging of PHBV/PLA blends-based graphene nanoplatelets and glassy carbon nanocomposites

Isabela Monteiro Cesar Oyama[1], Eduardo Ferreira Martins[1], Fabio Roberto Passador[1]

[1]Universidade Federal de São Paulo (*Departamento de Ciência e Tecnologia*)

e-mail: isabela.oyama@unifesp.br

The generation and accumulation of electrostatic charges is one of the main problems encountered in the production and operation processes in the electronics industry [1]. Antistatic packaging is used to protect electronic devices against damage caused by electrostatic discharges and these packages are generally produced with non-biodegradable polymers of fossil resource [1]. Thus, the production of packaging obtained from biodegradable materials constitutes a promising research area. In this work, two biopolymers were chosen: poly (lactic acid) (PLA) and poly (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV), both of renewable origin. Glassy carbon (GC) and graphene nanoplatelets (GNP) were chosen as antistatic agents. PLA/PHBV blends (80/20) with the addition of 0.1 and 0.5 wt% of GC and 3 wt% of GNP were prepared in a twin screw extruder (AX Plásticos, model AX16:40DR). Specimens were prepared by injection molding (Battenfeld, model Plus 350/75). The nanocomposites were characterized by tensile test, impedance spectroscopy (Impedance/Gain-phase Analyzer, model Solartron SI 1260) and Minimum Inhibitory Concentration test (using the following microorganisms: Escherichia coli ATCC 25992 and Staphylococcus aureus ATCC 6538). The addition of GNP and GC caused an increase in the elastic modulus of the nanocomposites. All compositions showed adecrease of 9 orders of magnitude in electrical resistivity (104 Ω.m), presenting the electrical properties for application as antistatic packaging. The compositions showed MICvalues greater than 70%, demonstrating their antimicrobial potential. PLA/PHBV blend withthe addition of 0.1 wt% of GC and 3 wt% of GNP showed optimization of properties, withhigher elastic modulus, low electrical resistivity and antimicrobial activity.

e-mail: juliagarciabranco@hotmail.com

With the increase in pesticide resistance, silver nanoparticles (AgNPs) have been widely used, mainly in the agricultural sector. The biogenic synthesis of these nanoparticles has a high antimicrobial potential and stimulates plant growth and nutrition. In the present study the AgNPs were synthesized using ***Bacillus thuringiensis***, ***Bradyrhizobium japonicum*** and ***Azospirillum brasilense***, and 1 mM silver nitrate as metallic precursor. After the synthesis, chemical characterization was performed to determine the hydrodynamic diameter, polydispersion index (PDI) and zeta potential. The antimicrobial effect with microorganisms ***Escherichia coli***, ***Staphylococcus aureus***, ***Pseudomonas aeruginosa*** and ***Candida albicans*** were evaluated by disk diffusion and minimum inhibitory concentration (MIC). Thein vitro biological activity was evaluated against the phytopathogenic fungi ***Fusarium oxysporum***, ***Fusarium graminearum,*** and ***Sclerotinia sclerotiorum***. Cytotoxicity and genotoxicity were evaluated with the 3T3 cell line by MTT and comet assays. Effects on seedgermination and growth were investigated with broccoli seeds. AgNPs showed a mean hydrodynamic diameter of 79.70±1.10 nm, PDI 0.51±0.01 and zeta potential of −33.30±0.78mV. Disk diffusion and MIC assays showed that AgNPs inhibited pathogenic microorganisms. AgNPs showed inhibitory potential against phytopathogens with greatereffect on ***S. sclerotiorum***. The IC 50 was found at a concentration of 33%, with no indicationof genotoxicity. Regarding the effects on seed germination, no significant differences wereobserved. This study paves the way for further investigations on biogenic AgNPs.

e-mail: goncalves.mk@hotmail.com

The availability of petroleum is declining, and the current technology is capable of recovering between 20 and 40 % of oil stored in reservoirs [1]. The present work aimed to produce and test nanofluids for the enhanced oil recovery (EOR), targeting the increase in recovery from mature reservoirs. Nanofluids (NF) were produced using nanoparticles of calcium oxide from Mytella falcata shells, derived from irregular discard in Alagoas State, which were used at concentrations of 0.05, 0.1 and 0.5 % (m/m), through the twostep method, where, after the nanoparticle conception as a powder, they are dispersed in the base fluid, at the proper concentrations. The nanofluids produced were evaluated in terms of nanoparticles surface composition, contact angle, recovery efficacy in a flooding assay using a simulated porous medium and alteration of conductivity. The XRD results indicated a characteristic Ca-O peak at 2θ = 32.1º, and the FTIR showed a strong stretch at 712 cm-1, this region is characteristic of CaO absorption bands. The wettability alterations were observed via contact angle analysis between the NF droplet and the saturated rock sample. The nanofluid at a concentration of 0.05 % had a decrease of 41.95º; 0.1 % reduce the angleby 36.57º; and at 0.5 %, there was a 44.12º decrease related to the base fluid, distilled water. This effect indicates a shift of wettability from oil-wet to water-wet, favouring the recovery of the oil impregnated into the rock. There was also

a rise in the base fluid conductivity, increasing the Brownian movements of the nanoparticles in the system. At last, the efficiency of oil recovery was improved by 8.5%, demonstrating the potential of the method in EOR.

CATIONIC EXCHANGE IN TITANATE NANOTUBES AND EVALUATION OF PHOTOCATALYTIC POTENTIAL IN DEGRADATION OF METHYLENE BLUE DYE

Mônica Hipólito da Silva[1], José Milton Elias de Matos[2]

[1]Universidade Federal do Piauí (*Química*) , [2]Universidade Federal do Piauí

e-mail: monicahipolito31@gmail.com

Water pollution with dyes has become a very frequent problem, bringing severe consequences to natural resources and human health, being often carcinogenic and very resistant in natural conditions and the treatment of polluted waters is a major challenge since these products are not biodegradable. Among the most appropriate techniques for dye degradation is photocatalysis. In this work was performed the synthesis of Titanate nanotubes by the microwave-assisted alkaline hydrothermal method and the cation exchange of Na^+ions by the metallic cations $Sr^{2+}$and Co^{3+}, the photocatalytic activity of the catalysts synthed in the degradation of the methylene blue dye.

TiNTs were synthed using microwave-assisted alkaline hydrothermal synthesis, using TiO_2as precursor and NaOH at 10 mol.L^{-1}. Ion exchange was performed by suspending NaTiNTs, previously synthed, to solutions of cobalt and strontium nitrates. Photolysis and photocatalysis were performed in a closed box with LED lamp (30 W), in which 50 mg of the catalyst was added to a 0.1 mmol solution. L $^{-1}$of the dye. Throughout the procedure the solution was oxygenated and kept under agitation at room temperature. Samples were collected during the process at specific times between 0 to 120 minutes.

The techniques used for the structural analysis of the materials were Raman and FT-IR. The results of the photolysis and photocatalysis tests were analyzed by UV-vis spectroscopy and the kinetic study with the degradation rate was performed. The synthesis of Titanate nanotubes from the hydrothermal method was efficient, as well as the ion exchange process of Na^+ions by $Co^{3+}$and Sr^{2+}ions. The Raman spectrum found that the structure of the nanotubes remains intact after their insertion. The pure and exchanged TiNTs showed good photocatalytic activity in the degradation of methylene blue.

Characterization of malachite pigment interaction with linseed oil hydrolysis/oxidation products in paints under accelerated aging - reflections on the conservation of cultural heritage

Thiago Guimarães Costa[1,2], Adolfo Horn Jr.[3], Christiane Fernandes Horn[3], Lucas Brandalise Menezes[3]

[1]Universidade Federal de Santa Catarina (*Química*) , [2]Fundação Catarinense de Cultura,
[3]Universidade Federal de Santa Catarina

e-mail: thiagocosta@fcc.sc.gov.br

The interaction between inorganic pigments and hydrolysis/oxidation products of polymerizable oils can be harmful to cultural heritage paintings [1]. In this work, the interaction of the pigment malachite green ($Cu_2(OH)_2CO_3$) with linseed oil submitted to accelerated aging was investigated [2]. This preparate ink was applied onto a 10x3 cm linen and aged at 105 °C for 5, 24, 168, 360 and 720 h corresponding to 2.25; 10.8; 75.7; 162 and 324 years of aging at 25 °C, respectively. For the sample aged 24 h, FTIR studies revealed new bands at 1716 and 1700cm^{-1}, indicating the presence of carboxylate groups, which is related to the hydrolysis/oxidation of the fatty acids. After 168 h of aging, bands at the range 1560-1575 cm^{-1}were observed, indicating the coordination of carboxylate groups tothe Cu(II) ions. SEM-EDS analysis shows that the 5h aged pigment has a non-uniform size distribution with a mean lateral particle size of 24.66 +- 7.12 µm and an increase in pigment agglomeration in the oil with increasing aging time reaching 46.44 +- 7.67 µm for the 720h aged paint. A remarkable difference is observed in the EPR spectra related to the Cu(II) signal in the samples after aging. For example, the original isotropic signal related to Cu(II) ion present in the malachite pigment changed to a rhombic signal after 5 h aging, whose simulation indicated the following EPR parameters: g_x= 2.08; g_y= 2.16 and g_z= 2.30 and A_x= 1.58 G, A_y= 66.48G and A_z= 163.08G. Together, the FTIR and EPR analyses showed that the copper(II) ion present in the malachite pigment undergoes a chemical reaction with the product of hydrolysis/oxidation of linseed oil, which results in pigment agglomeration and consequently, possible damages to the paint.

Characterization of Vale do Pindaré clay minerals forthe other industrial applications

Ronilson Lopes Brito[1], Enio de Vale Sales[2], Ayrton de Sá Brandim[3], Marcelo Moizinho Oliveira[4], José Hilton Gomes Rangel[2]

[1]Instituto Federal de Educação, Ciência e Tecnologia do Maranhão (*DAQ*) , [2]Instituto Federalde Educação, Ciência e Tecnologia do Maranhão, [3]Instituto Federal de Educação, Ciência e Tecnologia do Piauí, [4]Instituto Federal de Educação, Ciência e Tecnologia do Maranhão (*Departamento Acadêmico de Química*)

e-mail: ronilsonbrito@hotmail.com

Four Maranhense clays obtained from brickworks of the small pole of Vale do Pindaré were characterized in a preliminary way by several methods aiming at their potential application in filters for water treatment or other applications. The mineralogy, plasticity, porosity, and interaction of clay with other components determine its suitability for use as filters[1]. The chemical composition of clay minerals was quantified by XRF. In both types of clay and evaluated as plastic (CIGD and CEGD) of a darker color and non-plastic (CIMG and CEMG) of a more yellowish color. A percentage of the largest oxides of silicon (Si02), aluminum (Al203), and iron (Fe203) is obtained, these being the largest non-plastic ones. Other oxides are found (Ti02, MgO, K20) with levels above 1%, which can give good resistance characteristics, as well as a high level of Al203 in all samples (>20%), which contributes to the application of clay as filters, thus improving their resistance mechanical, in addition to being an important refractory lining. XRD showed quartz as the most abundant phase in clays, while in more plastic clays its concentration decreased systematically with the increase of other phases found such as kaolinite, orthoclase and magnetite. The thermal behavior of the clays determined by TG showed a continuous loss of mass, divided into two events easily identified in the DTG, with peaks close to 50 °C and 550 °C. The first, associated with a loss of adsorbed water (2-3%) and a loss of mass at higher temperatures around 12.6%, for plastic clays and a loss of mass of 37% and 4.61% for the non plastic clays, respectively, is associated with loss of organic matter and dehydroxylation of kaolinite[2]. Future applications in the production of filters due to the presence of ions of interest such as potential mechanical characteristics.

Characterization of ZnO thin films produced via an ultrafast and low-cost spray pyrolysis methodology

Gabriel Oliveira Machado[1], Adriano Borges Andrade[1], Tatiane Strelow Lilge[1], Mario Ernesto Giroldo Valerio[1], Zélia Soares Macedo[1]

[1]Universidade Federal de Sergipe (*Departamento de Física*)

e-mail: gabrieloliveira.machado2002@gmail.com

Zinc oxide (ZnO) thin films have been explored for several applications, such as sensors, solar cells, photodetectors, LEDs, photocatalysts, and others [1-3]. In this work, a homemade system of spray pyrolysis was mounted and used to produce ZnO films, deposited on a glass substrate of 0.5mm thickness. The precursor solution was zinc nitrate ($Zn(NO_3)_2$) dissolved in de-ionized water, with concentration of 0.1M. During the deposition, the substrate temperature was controlled (280°C and 320°C were tested) and after the deposition the sample was annealed at 350°C for 1h, in a muffle-type furnace. The crystalline wurtzite (ICSD #26170) was the single phase observed in X-ray diffraction (XRD) results, with preferential orientation according to the substrate temperature.The SEM images revealed the uniform deposition of the films and the characteristic rod-like shape ofZnO particles. The optical characterization was performed in excitation and emission modes. ZnO presented a broadband emission between 400 nm and 800 nm, which was enhanced by the annealing of the samples. This result was possibly associated to thecrystallization and grain growth of the ZnO nanoparticles. In conclusion, this methodologypresented several advantages, such as low-cost, easy operation, good reproducibility, andcontrol of the properties. The surface homogeneity was comparable or even better to theresults previously obtained using dip or spin coating methods. In the next step of this work,ZnO doped with transition metals are currently being produced and characterized, to beexplored as photocatalists.

Chemical, structural and photophysical investigation of the novel mixed-metal Eu^{3+}/Sb^{3+} layered rare earth hydroxides

Carlos Americo Lechuga Puma[1], Maria Eduarda Silvestre Duarte[1], Rodrigo da Silva Viana[2], Camila Braga Dornelas[1,2]

[1]Institute of Pharmaceutical Sciences, Federal University of Alagoas, Maceió, Brazil,
[2]Technology Center, Federal University of Alagoas, Maceió, Brazil

e-mail: qflechuga@gmail.com

Layered rare earth hydroxides (LREHs) are a family of anion-exchangeable 2D inorganic materials that have been the object of interest for their new and adapted electrical, magnetic and optical properties in different fields of materials science [1]. Regarding the fluorescent properties of LREHs, the use of Sb^{3+}as sensitizing centers for Eu^{3+}has not yet been explored despite that the ns^2electronic configuration has resonant states with the Eu^{3+}energy levels and this can lead to efficient energy transfer processes (ET)[2]. In this work were obtained a series of LRHs heterometallic hydroxides ($LEu_{1-x}Sb_xH-Cl$ (x = 0.05, 0.10, 0.15, 0.20, 0,25, and 0.30) through hydrothermal treatment to examine the influence of the physicochemical properties and the ET resulting from the incorporation of Sb^{3+}. XRD for $LEu_{1-x}Sb_xH-Cl$ showed characteristic planes of the $Yb_8(OH)_{20}Cl_4{\cdot}nH_2O$ (orthorhombic crystal system; $Pca2_1$space group) corresponding to the crystallographic data. FT-IR spectra for $LEu_{1-x}Sb_xH-Cl$ revealed a band between 473-600 cm^{-1}related to M–O (M = Eu and/or Sb) and a signal between 3500-3750 cm^{-1}corresponding to the –OH band. EDS spectra show the presence of Sb and Eu for all $LEu_{1-x}Sb_xH-Cl$. Photoluminescence of $LEu_{1-x}Sb_xH-Cl$ reveals the characteristic *f-f* transitions $^5D_0\rightarrow{}^7F_{0-4}$from Eu^{3+}ion. On the other hand, excitation spectrum(λ_{Em}= 618 nm) revealed, in addition to the Eu^{3+} *f-f* intra-configurational transitions, a progressive increase of the band centered at 274 nm (Sb^{3+}: $^1S_0\rightarrow{}^3P_1$) suggesting a possible ET: $Sb^{3+}\rightarrow Eu^{3+}$. In short, it was performed for the first time a chemical, structural and photophysical spectroscopic study of $LEu_{1-x}Sb_xH-Cl$, revealing the influence on Sb3+ incorporation.

Geopolymers are inorganic materials formed by a rich source of silicon and aluminum with an alkaline solution, by virtue to their strong bonds, these materials have chemical inertness, durability and high mechanical resistance. Blast furnace slag and steelmaking slag are industrial by-products that have a high calcium content in their structure, which promotes increased mechanical strength in the structure of geopolymers due to microstructural compaction. In this comparative work, the properties of compressive strength and microstructure of geopolymeric cements with addition of blast furnace slag and steelworks slag were studied. The specimens were tested after seven days of curing,and soon after the test, the fragments were taken for optical microscopy for microstructural evaluation. The cement with the addition of blast furnace slag obtained better mechanical performance, about 24 MPa, as well as a microstructure with few pores and more compact, when compared to the geopolymeric cement with the steel slag.

The direct casting of aqueous suspensions uses binders (hydraulic or colloidal) to set the structure, avoid drying shrinkage, and assure strength for demolding. Hydraulic binders are anhydrous oxides that react with water to harden the structure. The most used hydraulic binders in the refractories are calcium aluminate cement (CAC) and hydratable alumina (HA). Colloidals comprise nanod particles dispersed in a liquid phase that can be chemically gelled. For colloidal silica-bonded systems (CS) particles' gelling does not involve hydroxylation reactions. Due to this, the high-permeability structure generated reduces the pressurization by water vapor during drying. This work compared the physical properties of calcined alumina suspensions cast using HA or CS as binders after isothermal treatments (120-1600°C). Up to 900°C, CS-bonded samples showed the highest levels of elastic modulus. For the CS ones, the viscous sintering of SiO2 nanoparticles increased the rigidity, despite the higher total porosity levels. Above 900°C, HA-bonded samples became strongerdue to the early sintering, at the same time, in situ formation of mullite in CS-bonded-ones difficulted particles' densification due to its low density.

High entropy materials (HEM) can be obtained from several chemical elements, and commonly have a simple crystalline structure. In this group of materials, high configuration entropy can be obtained by equimolar mixing of constituents that hinder phase segregation at high temperatures, thus increasing the solubility of the components. In this work, high entropy oxide powders (Mg0,2Co0,2Ni0,2Cu0,2Zn0,2)O were synthed by the polymeric precursors. To sintering, the calcined powders were uniaxial compacted with a pressure of 80 kgf/cm³ in a cylindrical format, resulting in green ceramics measuring 4 mm in diameterby 1.0 mm in thickness and relative density of approximately 60%. The green ceramics were sintered using two methods: conventional sintering in electrical furnace at 1100 °C/2h, 1150 °C/2h and 1200 °C/2h; and by laser sintering, in which a CO2 laser is used as heating source, at different power density. The relative density of the sintered ceramics produced bythe both techniques was 85%. The samples were characterized by X-ray Diffraction (XRD),Scanning Electron Microscopy (SEM), Energy Dispersion X-ray Spectroscopy (EDS) and Impedance Spectroscopy (IS). XRD results confirm the formation of a single cubic crystalline phase (Fm-3m) [1] in all ceramics. Laser-sintered ceramics presented a smallergrain and lower surface porosity than conventionally sintered ceramics. EDS mapping images reveled a segregation of Cu at grain boundary associated with a relative decrease ofthe other ions [2].

Gold nanoparticles (AuNPs) are nanostructures with intrinsic optical properties attributed to localized surface plasmon resonance (LSPR). This phenomenon is provoked by the quantum confinement of electrons resulting in the appearance of bands (transverse and/or longitudinal) as a consequence of the excitation of AuNPs by electromagnetic radiation in the visible region [1]. Polymyxin B is a cationic polypeptide antibiotic used in last-resort therapies. The main objective of this work was to study the behavior of gold nanoparticles (AuNPs) to evaluate their potential as sensors for the quantification of traces of the antibiotic polymyxin B, using fluorescence as a parameter for the quantification of the contaminant [2]. The formation of pairs with the cationic dye Rhodamine B were based on fluorescence resonant energy transfer (FRET systems)-based processes for pairs of rhodamine B (donor) and acceptors of citrate capped gold nanoparticles (AuNPs) through incorporation progression of the analyte. Strong fluorescence activation was observed for polycationic species of polymyxin B whose detection limit is around 0.7 ppm, being the system satisfactory for detecting traces of polymyxin B.

The increasing demand for energy, coupled with growing concerns about the state of the environment and its impact, have intensified the need for renewable energy sources. As a result, research into the development and improvement of these sources is of great importance [1,2]. Most solar panels in use today are based on silicon (Si) and have limited absorption in the ultraviolet (UV) region, where the sun has strong emission. However, its highest absorption peak is in the near-infrared (NIR) region [3]. Given this consideration, the aim of this work is to develop mechanisms such as systems based on down-conversion and quantum-cutting to convert high-energy photons into lower-energy photons, to increase the efficiency of solar cells. For this purpose, many NaYF4 nanoparticles were synthed and doped with Ytterbium and different combinations of other rare earth ions, including Erbium, Neodymium, Cerium, Thulium, Manganese, and Gadolinium, all of them in their trivalent form. The idea is that these other rare earth ions absorb high-energy photons and, through non-radiative process, can transfer their energy to the ytterbium ions, which emit strongly in the IR region. As a result, we successfully obtained that, under UV excitation or by excitation with a white light source, characteristic emissions of Ytterbium ions were observed. The next step in the work will be to find the best combination of these ions and optimize their concentrations.

Development and characterization of model drilling fluid based on oxidized hexagonal boron nitride (h-BN-oxi)

Ultra-deep water exploration has become necessary due to the rising demand for oil and difficulty in extracting it from onshore fields.[1] However, it poses challenges such as drilling through salt formations and environmental issues.[2]

The drilling fluid plays a crucial role in cooling the bit, transporting cuttings, and stabilizing rock formations. Moreover, the drilling process experiences elevated temperatures and pressures and one of the major challenges is to maintain the rheological properties of drilling fluids. To address these issues, companies have adopted nanotechnology-based solutions to develop fluids capable of operating at high pressure and temperature while ensuring material stability. One promising material is hexagonal boron nitride (h-BN), which is highly inert, non-toxic, and exhibits good thermal stability and hardness.[1] This work aims to develop oxidized hexagonal boron nitride (h-BN-oxi)/xanthan gum nanostructured model fluids to understand their rheological and thermal properties. Morphological and structural characterization of the model fluids was performed and related with the rheological studies.

Mesoporous silica nanoparticles have attracted interest from several areas of knowledge, including, but not limited, pharmaceuticals and cosmetics [1], due to their characteristics such biocompatibility, large surface area, enabling the functionalization and loading of bioactive molecules [2]. Thus, the objective of this work was to develop MCM-41 functionalized with chitosan (MCM-41@Ch) for drug release control. The synthesis of the MCM-41 type silica nanoparticles were developed by the sol-gel method using cetyltrimethylammonium bromide (CTAB) as a template, at mild temperature, involving hydrolysis and condensation reactions of tetraethyl orthosilicate (TEOS), precursor of silica. A 1% chitosan solution was prepared [3]. Subsequently, the 1% chitosan solution was used to functionalize MCM-41. Characterization tests carried out were FTIR spectra using a Shimadzu IR Prestige-21 spectrophotometer; XRD was made from a Shimadzu XRD-6000 x-ray diffractometer using CuKα radiation and λ=1.79 Å. TEM images were obtained using a transmission electron microscope Tecnai Spirit T12 analysis. XRD' result confirmed the formation of silica nanoparticles with hexagonal structure p6mm of ordenaly way, being a pore surrounded by six others pores. The TEM images of unmodified MCM-41 and the surface modifie nanoparticles (MCM-41@Ch) demonstrated that all of them showed uniform and spherical shape and have an average particle size. With the FTIR analysis was possible to investigate the functional groups and connections chemicals present in the samples. It wasconcluded that the MCM-41 particles reached a nanometric scale, as well as the functionalization with chitosan was achieved and that they can be used for the production of medicines and/or cosmeceuticals.

Non-toxic ammunition (NTA) has been developed to protect the health of security agents as well as the environment itself. However, gunshot residues (GSR) generated by NTA ammunition has a certain level of difficulty when it comes to their unambiguous identification. To bypass this problem, the use of luminescent markers in ammunition has been proposed. These markers bring with them an advantage in the matter of identification, by allowing the convenience of visualizing them using only a portable ultraviolet lamp, facilitating the ability to collect directly on site for subsequent analysis in the laboratory.[1-2] In this work, the use of complex β-dicetonates as luminescent markers of ammunition was proposed. The complex β-dicetonates of Europium, $Eu(BTFA)_3bipy$, $Eu(BTFA)_3phen$ and $Eu(BTFA)_4$were synthetized, characterized and had their effectiveness as markers in assessed ammunition. The complexes containing 2.2'- bipyridine and 1.10-phenantroline were synthesized using a reflux system at 60 °C, while the $Eu(BTFA)_4$was synthetized using the same system, but at ambient temperature. Both of them are easily scalable for an industrial situation, the latter having the advantage of being able to be synthesized without the need for heating. The results of their characterizations before and after the shots showed that these three complexes are feasible as luminescent markers.

Electrochemical technology is a great method for degradation of complexes and stables pollutants [1]. This work aimed the development of Fe, Co, Ti, Ni and Cu oxides-based electrodes, in binary and ternary compositions, for degradation of organic pollutants in water. The sun-yellow dye was the model pollutant. New materials were deposited into titanium plates and obtained by thermal decomposition at 400 ºC. These materials were analyzed as anode and a commercial DSA as cathode. Electrochemical characterization was performed in H_2SO_4 0.5 mol L^{-1}. The assays were realized for 2h in Na_2SO_4 0.1 mol L^{-1}, $j = 15$ mA cm^{-2}, at ambient temperature, under magnetic stirring and with no pH adjustment. For the electrodes analyzed, mean color removal rate were over 90% with good reproducibility. The open-circuit potential values obtained before and after the oxidation reactions presented low variation for the compositions Co-Fe, Ni-Ti-Fe and $Ti/Cu_{0.5}Fe_{0.5}O_2$. No correlation between the electroactive area and the electrocatalytic efficiency was observed. This suggests that the most crucial elements for the efficiency and stability are the generated oxide types and their crystalline structures. For the anode $Ti/Ni_{0.3}Ti_{0.2}Fe_{0.5}O_2$, the dye initial concentration decay data was best adjusted for the pseudo-second order, meanwhile, for the others, the pseudo-first order was a better fit. The results show that the materials are efficient and stable as anodes in the electro-oxidation. In addition, the small cost of the reagents needed to synthetize them, promote the possibility ofa simple, effective and accessible alternative to the wastewater treatment through electrochemical technology.

A metal surface can exhibit low wettability through the formation of a hierarchical roughness structure in the micro/nanometer dimensions in association with a surface energy-reducing agent. When the contact and slip angles are ≥ 150° and ≤ 10°, respectively, the surface is characterized as superhydrophobic. [1,2] Superhydrophobicity gives the surface a self-cleaning effect, where water is highly repelled, protecting the metal substrate from direct contact with corrosive electrolytes. Among the ways to coat a material, electrodeposition stands out by presenting good versatility, low cost, relatively simple industrial application, and has shown to be an emerging technique to produce nanocomposite materials in several areas of materials engineering [2,3]. In this study, coatings containing nickel stearate and nickel stearate with multiple-walled carbon nanotubes were applied via electrodeposition in alcoholic solution on aeronautical aluminum alloy 7050. Contact angles of up to 160° (about twice as large as the uncoated substrate)and sliding angles of approximately 1° were obtained. Scanning Electron Microscopy (SEM)and Energy Dispersive Spectroscopy (EDS) analyses confirmed the presence of a hierarchical roughness structure resembling a cauliflower, responsible for conferring the superhydrophobic characteristic, formed by peaks characteristic of the elements Ni, Cl, C and O. The results of X-ray diffraction (XRD) showed the presence of peaks characteristic of nickel phases, proving the reduction of nickel ions on the aluminum surface.

Antibiotics such as those from the tetracycline family, especially doxycycline, are widely used to treat various bacterial infections. However, their low stability is a challenge for the pharmaceutical industry, which can induce their degradation during the manufacturing process or storage. The formation of complexes stands out among the strategies studied to overcome the problem. This work investigated drug/clay complexes (DTC/VEEGUM and DTC/SEP) as photoprotector. The adsorption was performed using 2g of clay in 2g$L^{-1}$of the drug under agitation for one hour of reaction. Light stability tests were performed using a 125W lampless lamp as the UV radiation source for up to 200h. Photostability monitoring was performed using DRX, TEM, and BET. The XRD results showed changes in the crystallographic planes of the samples in the DTC/VEEGUM system before and after incorporation, but little change as a function of irradiation time, indicating its stability under UV light, as for the DTC/SEP system not. The TEM images corroborate the data observed in the XRD. In general, the specific surface area experimental data showed that the DTC load on the clays decreased the samples'' specific surface area and the total pore volume. This observation suggests that the pores were blocked upon embedding. It is concluded that DTC was successfully incorporated into the clay minerals under study from the evaluated systems. The DTC/VEEGUM interaction product showed more excellent stability to UV radiation, which may be due to its internal surface and the interlamellar space in its structure.

Effect of Ag nanoparticles on the electrochemical activity of a hybrid ormosil film with phosphomolibdicacid

Giovanni Gomes Daniele[1], Gabriel Vinicius Buzato[2], Adriano Lopes de Souza[2]

[1]Universidade Federal de São Carlos - Campus Araras (*DCNME*) , [2]Universidade Federal de São Carlos - Campus Araras

e-mail: giovannigomesdaniele@gmail.com

Hybrid thin films formed by polyoxometalates (POMs) immobilized in an organically modified silicate (ormosil) network have been used in applications as photo and electroactive devices [1,2]. The employment of metallic nanoparticles in films containing POMs can improve the electroactive activity of a hybrid film [3]. Very few experiments, however, show electrochemical properties of a hybrid ormosil film containing POMs and metallic nanoparticles, such as silver nanoparticles (Ag NPs). In this study, we investigated the electrochemical response of a hybrid ormosil film containing phosphomolybdic acid (HPMo), a Keggin type POM, and Ag NPs immobilized in an ormosil network formed by tetraethyl orthosilicate and 3-Glycidoxypropyltrimethoxy silane. The electrochemical properties were analyzed by cyclic voltammetry and differential pulse voltammetry. The results showed that in the hybrid ormosil film containing Ag NPs, the current density was 20,19% higher than the hybrid ormosil film without AgNPs. It was demonstrated that the hybrid ormosil film with AgNPs could be used to develop electrochemical devices and in future applications in this area.

e-mail: viniciustartare.ufscar@gmail.com

Bile salts are surfactants produced by the liver, being important as drug delivery platforms [1]. Above the critical micellar concentration (cmc), they can form self-aggregates and have the structure altered by intermolecular interactions with substances [2] such as cellulose nanofibrils (CNF), creating procedures for obtaining rheological modifiers. In this work, CNF in the concentrations of 0.96, 2.40 and 4.80 g L-1 was mixed with sodium taurodeoxycholate (NaTDC) or sodium deoxycholate (NaDC) in order to evaluate the viscoelasticity of the systems by rheological measures. Flow curves of all systems showed that the apparent viscosity increased with the increment of CNF. Furthermore, the systems presented the phenomena of shear thinning followed by shear thickening, indicating the non-Newtonian behavior of fluids [3]. The viscoelasticity of the systems was confirmed by rheological curves in the oscillatory mode and the increment of CNF amount increases the viscoelasticity of the systems. But, CNF/NaDC systems presented more structured than CNF/NaTDC, since the elasticity modulus G’ increases. This suggests that, in the presenceof nanocellulose, NaDC self-aggregates are longer than bile salt with the taurine group, perhaps, due to the less negative charge in the NaDC structure. In short, CNF associated with both bile salts can form different structures depending on the proportion of the nanoparticles, modulating the rheological behavior of the systems. Then, different bile salts can be promising systems for rheological modifiers depending on the objective of application.

Understanding the behavior of nanoparticles (NPs) in aqueous suspensions is a crucial step for many applications. Compared to bulk materials, NPs exhibit distinct characteristics that must be evaluated due to their highly reactive nature [1]. After going through a milling ball process in order to break up agglomerates and achieve particles of uniform on a nanoscale [2], some dispersing method were tested on nano niobium pentoxide (Nano-Nb2O5). The hydrodynamic and distribution of the resulting dispersion were analyzed using dynamic light scattering (DLS) with different ultrasonication methodologies (Bath and Tip Ultrasonicator) for 5, 10, or 15 minutes, and with the use of a Polycarboxylate-based superplasticizer (SP) as a stabilizing agent. The dispersion s were also analyzed after 4 hours of sonication. The DLS results revealed that the application of sonication reduced the agglomeration of Nano-Nb2O5 for all durations tested. Interestingly, it was observed that the sonication process for 5 minutes yielded comparable results to those obtained with longer durations. However, after 4 hours, it is possible to observe sedimentation and agglomeration advance. The addition of the superplasticizer ensured the stability of the nanoparticle dispersion, preventing agglomeration again.

High temperatures and pressures can be reached by cavitation bubbles from laser ablation in liquid environment (PLAL). The plasm and radical specimens raised from that process have been used to obtain metallics and oxides nanoparticles and to carry out chemical reactions in a non-conventional rout [1]. Matal organic frameworks (MOFs) is an important class of highly porous hybrid materials able to be obtained by laser ablation [2]. Recently, new MOFs based on bismuth and benzene-1,3,5-tricarboxyic acid (BTC) have been developed and laser ablation was applied to obtain Bi-BTC MOF in DMF/methanol liquid environment from bismuth target ablation [3,4]. Therefore, the effect of solvent has been less explored to investigate the MOFs structures obtained by laser ablation. This research presents results of bismuth MOFs obtained by laser ablation of powder bismuth oxide in three different solutions of BTC (DMF/methanol, DMF/ethanol and DMF/water) using a second harmonic (λ = 532 nm, 100 mJ) of a pulsed Nd:YAG laser. The scanning electron microscopy (SEM) presented sheet structures to Bi-BTC obtained in DMF/water and powder microstructure in DMF/methanol and DMF/ethanol. The samples were analyzed by FTIR, Raman, TGA and XRD, confirming different kinds of Bi-MOFs structures were found as a function of liquid environment.

Acknowledgments

e-mail: buzatogabriel@estudante.ufscar.br

Hybrid layer-by-layer (LBL) films with polyoxometalates (POMs) have attracted much interest because of their wide range of applications as electroactivity for triazinic compounds [1,2]. Nitrite (NO2-) is generally used as food preservative and some studies have described its excessive consumption to the development of gastric cancer [3]. Hybrids in the form of LBL films formed by metallic nanoparticles (NPs) and POMs have not had their electroactive properties investigated in detail yet. In this study we aimed to investigate the electrochemical reactivity of films containing poly(amidoamine) (PAMAM) and silver NPs with phosphomolybdic acid (HPMo), a Keggin-type POM, toward nitrite. Cyclic voltammetry was used to explore the electrochemical properties of this hybrid film at pH 1.0. Results showed that nitrite was electroreduced by the film containing three bilayers of PAMAM, HPMo and silver NPs at -0,06 V vs. Ag/AgCl in the concentration range from 40 µmol L-1 to 234 µmol L-1. The LBL film containing PAMAM, HPMo and silver NPs showed higher sensitivity towards nitrite in comparison to the film without silver NPs with values of 5,20x10-4 µA cm-2 µmol-1 Land 1,07x10-4 µA cm-2 µmol-1, respectively. Our experiments demonstrate that this LbL film could be employed in systems for food and health applications.

The study of quantum thermal machines, devices such as quantum engines and refrigerators that operate on working mediums composed of quantum systems, has proved to be a fruitful research area in the last decade [1]. These efforts have been focused principally on the study of the different thermodynamic cycles, such as the Otto and the Stirling cycles, in different regimes [2] and on the use of different quantum working substances such as spins, quantum dots [3], and quantum harmonic oscillators. Recent work has also examined the role that quantum properties, such as quantum coherence and quantum correlations, play in the performance of quantum thermal machines [4]. A primary feature of interest of quantum thermal machines is their potential to surpass the performance of their classical counterparts, which opens the door to a new generation of highly efficient quantum engines and refrigerators for application in emerging quantum technologies. In this work, we study the performance of an endoreversible magnetic Otto cycle with a working substance composed of a single quantum dot described using the well-known Fock-Darwin model. We find that tuning the intensity of the parabolic trap (geometrical confinement) impacts the proposed cycle’s performance, quantified by the power, work, efficiency, and parameter region where the cycle operates as an engine. We demonstrate that a parameter region exists where the efficiency at maximum output power exceeds the Curzon-Ahlborn efficiency, the efficiency at maximum power achieved by a classical working substance.

Evaluation of materials applied in the removal ofsodium diclofenac concentration.

Diclofenac sodium is a widely used non-steroidal anti-inflammatory drug that can be found in water from rivers, lakes, and other sources. Therefore, the evaluation of materials applied in the removal of sodium diclofenac concentration involves both the study of different techniques and materials and the determination of removal efficiency, kinetics of adsorption or degradation, regeneration capacity and stability of the material under environmental conditions. Among the techniques used, adsorption on solid materials, advanced oxidation and heterogeneous photocatalysis stand out. In adsorption, the solid materials used have a high adsorption capacity (better put how the adsorption takes place) and can be reused after regeneration. In advanced oxidation, the drug is degraded through chemical reactions that use oxidants such as ozone, hydrogen peroxide and free radicals. In heterogeneous photocatalysis, drug degradation occurs through exposure to light, in the presence of catalysts such as titanium dioxide. Materials are chosen based on the conditions of use, the characteristics of the drug to be removed and material properties, such as, for example, adsorption capacity, stability and ease of regeneration. Therefore, some of the materials used in the removal of diclofenac sodium are activated carbon, zeolites, silicas, polymers and nanomaterials. Therefore, these studies are fundamental for the development of efficient and sustainable processes for the removal of sodium diclofenac and other contaminants emerging from water.

Evaluation of the adsorptive potential to atrazine of demolition and construction waste from State of Alagoas

Sabryna Gomes de Alencar[1], Laura Layne Pinheiro Veiga[2], SENDY MELISSA SANTOS DO NASCIMENTO[3], Eduardo Jorge da Silva Fonseca[3], Leonardo Mendonça Tenório de Magalhães Oliveira[4], Liz Araujo[5], Herica Santos[5]

It is estimated that the civil construction industry in Brazil is responsible for generating 2.65 billion tons of total waste per year [1]. In addition, due to excessive use in agriculture, several bodies of water are now registering the presence of atrazine, an herbicide with the potential to be toxic to fauna and humans. [2]. Thus, this work evaluated the feasibility of applying construction and demolition waste (CDW) from Maceió/AL - Brazil as adsorbents in the removal of atrazine from aqueous matrices. The material was standardized to 0.59 mm, characterized, and tested for affinity with 10 ppm atrazine solutions at pHs 3, 7, and 11 in batch system. To evaluate the potential for industrial use, the material was applied in a fixed bed column (Di = 1.27cm, L = 5.0 cm) under a flow rate of 29.41 mL/min. It was noted that the material presented functional groups characteristic of clay mineral compounds, with absorption bands indicating O-Al, O-Fe, CaO and CaCO3. Little evidence of organic functionalization was identified. Superficially, the RDCs were not very porous and highly rough, and the batch affinity tests indicated that the material has a better adsorption potential at acidic pH, with a removal of 47%. In the fixed bed tests, percentages of removal in the range of 39.5% were observed, suggesting their applicability in the separation of a potentially present pollutant in water bodies and industrial effluents. Besides, the study opens the possibilities of converting heterogeneous waste like CDWs to full adsorbents.

Non-Toxic Ammunition (NTA) was developed to protect the health of public safety agents and the environment. However, the methodologies employed for the identification of gunshot residues (GSR) have become inefficient when using this type of ammunition. In order to solve this problem, the implementation of luminescent markers in ammunition was presented as an alternative. These markers are known for allowing the visualization of residues at the crime scene using only an ultraviolet (UV) lamp, facilitating the visualization, collection and subsequent analysis of residues in the laboratory [1-3]. In addition, the waste generated can be characterized by various non-destructive analytical techniques available in the main expertise centers in Brazil [2]. The objective of this work is to evaluate the efficiency of the lanthanide β-diketonate complex (Eu(btfa)$_3$bipy) as a luminescent marker for shot residues. The results show that the Eu(btfa)$_3$bipy complex is an efficient luminescent and chemical marker, and its characterization can be applied to routine forensics.

Keywords: β-diketonates, lanthanides, luminescent marker, gunshot residues (GSR), forensic investigation.

e-mail: alissonrios@ufpa.br

In the present work, flexural and fatigue tensile tests were carried out to evaluate the mechanical properties of Geopolymer Cement Concrete (GCC), which had characteristics compared with Portland Cement Concrete (PCC) [1], [2], [3]. The fatigue study was carried out by means of dynamic tests, in both types of concrete, evaluating the effects of different ages (1, 7 and 28 days), variation of minimum applied stress levels ($R=(\sigma min/fct,m)$) of 0.07, 0.20 and 0.40 and two percentages of steel fiber addition (0.5% and 1%). The fatigue results at different ages showed that the CCG has a better performance at all evaluated ages. The values found in the CCG were 13%, 96% and 24% higher than the values found in the CCP, at the ages of 1, 7 and 28 days, respectively. Regarding the minimum applied voltage, the average of the results showed a better performance of the CCG in relation to the CCP, presenting values 50% higher. Regarding the study with the addition of metallic fibers, the statistical values showed that the CCP and CCG had similar values. However, when observing the average values, it is possible to see the best results of the CCG in relation to the CCP, in the two percentages evaluated. In the microstructural analysis of the concretes it was possible to observe the better adhesion matrix-aggregate and matrix-fiber in the microstructure of the CCG, in comparison with the microstructure of the CCP, by virtue the absence of formation of crystalline phases in the matrix-aggregate and matrix-metal fiber interfacial region.

e-mail: isabel.malta@ufpe.br

Various natural systems possess properties of great interest to industry and academia, such as self-regeneration, camouflage, high adhesion etc. Biomimicry consists in transferring those biological strategies to products, technologies, and other fields to solve practical problems. Certain plants, such as Nelumbo Nucifera or Salvinia Molesta, exhibit superhydrophobicity, which is the ability to repel water, inspiring the production of new materials with properties such as anti-corrosion, anti-biofouling, and self-cleaning.[1,2] In this study, aluminum 5052 substrates were modified to achieve and characterize superhydrophobic surfaces while evaluating the Lotus and Salvinia Effects on the properties of the obtained coatings. The AA5052 samples were modified by means of chemical attack using HCl (2M), formation of a layered double-hydroxide (LDH) film in a solution of zinc nitrate with ammonium hydroxide (1M), and finally, reduction of surface energy using lauric acid solution (0.028M). Morphological and chemical characterizations by SEM and EDS, potentiodynamic polarization and visual tests were conducted. The coatings exhibited self-cleaning behavior (Lotus Effect) as well as the formation of an air pocket when immersed in water (Salvinia Effect) due to their high-water repellency, with a contact angle of 162°. The morphology of the coating showed micrometric flowers with hexagonal nanometric petals that allow air trapping according to the Cassie-Baxter model of wettability. Through Tafel parameters, the improvement in anticorrosive behavior was confirmed, with a corrosion resistance efficiency of 81.24%.

NiZn ferrite is an easily obtainable and relatively inexpensive material, making it a viable choice for many electronic applications, such as transformer and inductor core material, to suppress electromagnetic interference (EMI) and to reduce noise in electronic circuits [1,2]. Mn doping can be applied as a specific technique to optimize this NiZn ferrite in terms of its magnetic properties and thermal stability. In this study, ferrite Ni0.5-xZn0.5-xMn2xFe2O4 (x=0.1 and 0.15), that is, NiZn doped with 0.2 and 0.3 mol of Mn, was synthesized by combustion reaction in pilot scale, and sintered at 1200°C/1h. Afterwards, the samples had their structural, textural and magnetic properties evaluated. In this sense, the samples were analyzed by XRD, nitrogen adsorption/desorption (BET/BJH) and magnetic measurements (VSM). The results confirmed the monophasic formation of the studied nanoferrites, with crystallite s ranging from 33 to 57 nm and crystallinity from 45 to 82%, thus confirming the efficiency of the synthesis by combustion reaction. The samples showed particle ranging from 0.02 to 0.16 nm and surface area from 5 to 64 m2/g, where the larger the particle , the smaller the surface area. It was observed that both the introduction of manganese and the heat treatment favored the increase in the saturation magnetization of the samples, whose values ranged from 22 to 86 emu/g. Therefore, these results may be relevant for the development of large-scale NiZnMn ferrites with suitable properties for various applications.

Exploring the Potential of P-type Schwarzites for Selective CO_2 Adsorption: A Molecular Dynamics and GCMC Study

Aelton Baptista Santos[1], Pedro de Camargo Mazon[1], Cristiano Francisco Woellner[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: aeltonbaptista@hotmail.com

Transportation and storage of CO_2 has become increasingly important due to the ever growing concern over anthropogenic greenhouse gas emissions [1]. In this work, we explored the potential of Schwarzites, three dimensional crystalline carbon structures initially proposed in 1991 by Mackay and Terrones [2], for the selective adsorption of CO_2. Specifically, we focused on the P family of Schwarzites, including the P8-1, P8-3 and P8-7, which have already demonstrated promising properties for CO_2 adsorption in previous studies. Using molecular dynamics and Grand Canonical Monte Carlo (GCMC) simulations, through the widely used Lammps tool [3], we looked at the adsorption of CO_2, as well as N_2 and O_2, at pressures ranging from 0.01 to 50 bars and a temperature of 300K. Our results showed the P8-3 to be generally the most interesting, presenting high capacity and selectivity for CO_2 adsorption, demonstrating the potential of Schwarzites as efficient materials for carbon capture and storage.

In this work we used the synthesis process by combustion [1] in a digital muffle furnace (SolidSteel-SSFM (100°C-1200°C) with temperature control and stable atmosphere. The following reagents were used in this work: Ferric chloride ($FeCl3.6H2O$) P.A. , Cobalt acetate ($Co(C2H3O2)2.4H2O$) P.A., silver nitrate ($AgNO3$) P.A., and the catalyst fuels urea ($CH4N2O$) P.A. and citric acid ($C6H8O7.H2O$). The masses were made in the proportion of 1:1:1:3 respectively. After being homogenized in a pestle, they were inserted into a crucible and underwent the catalyst activation process, initially at a temperature of 120°C for 20 minutes four times. After this step, calcination was performed at 150°C once for 10 minutesand at 200°C for 20 minutes. The samples after synthesis were characterized by XRD, EDS,FTIR, UV-Vis-NIR, TEM and scanning microscopy. Optical microscopy observations were also performed. XRD measurements showed that the structure (FeOCoAg) was evidencedusing the Rietveld refinement method. The fluorescence measurements showed the atomic constituents with their respective energies for Fe, O, Co and Ag. FTIR measurements showed the presence of metallic compounds in the low wavenumber region. The UV-Vis-NIR measurements showed that the GAP energies present energy around 3.8 eV. The TEM measurements showed the morphology of the sample and after making the lognormal adjustments of the diameter distribution, it showed a mean diameter of 15 nm. Scanning microscopy showed that the morphology of the nanoparticles has spheroid surfaces.

e-mail: livia.elias@iqb.ufal.br

The development of fluorescent nanothermometers has been extensively studied due to their non-invasive measurement, wide temperature range and high resolution [1]. In this sense, carbon dots are excellent candidates to act as fluorescent nanothermometer due to excellent optical properties with tunable fluorescence, biocompatibility, photostability, and high dispersion in water [2]. In this work, a fluorescent film based on carbon dots (CDL-F) derived from lemon peel extract embedded in the polymer (PVA; poly (vinyl alcohol)) has been applied as luminescent nanothermometers. TEM micrographs for CDL revealed a particle distribution of 2.47 ± 0.47 nm and regular spherical morphology. FTIR spectrum showed the presence of the characteristic organic functional groups from the lemon extract: OH (3440 cm^{-1}), C–H (2930 cm^{-1}), C=O (1720 cm^{-1}), C=C (1400 cm^{-1}), and C–N (1200 cm^{-1}). Furthermore, the CDL showed absorption bands related to $\pi \rightarrow \pi^*$ (C=C) and $n \rightarrow \pi^*$(C=O/C-N) transitions. CDL exhibited excitation-wavelength-independent emission with maximum intensity at 446 nm (λ_{exc}= 336 nm). On the other hand, CDL-F showed excellent transparency, flexibility, and fluorescence in the blue region, which was similar to CDL in colloidal suspension. CDL-F also shows temperature-dependent fluorescence intensities between 298-333 K with a maximum relative thermal sensitivity of 2.69 % K^{-1}at 333 K and was stable over five cycles. In addition, MTT assay using a human non-tumoral skin fibroblast cell line (HFF-1) showed viability greater than 85 %. Finally, the recent results obtained indicate that CDL-F presents itself as a promising platform for luminescence thermometry applications.

Gelcasting colloidal silica-sodium alginatemacrospheres

Crislayne Gabriela Andreto[1], Ana Carolina Figueiredo Prado[1], Leandro Fernandes[1], Isabela Martinatti[1], Rafael Salomão[1]

[1]School of Engineering of São Carlos

e-mail: crislayne.andreto@usp.br

Ceramic macrospheres (0.1 1 mm) can be used as proppants for shale gas extraction, elements for milling, polishing, and fluidized bed process, and loose-fill insulation. Gelcasting is a method in which a suspension of ceramic particles containing a dissolved cross-linkable polymer is dripped and gelated in contact with an ionotropic coagulating bath. The beads produced show great control in chemical composition, geometry dimension, and concentration of defects. This study evaluated the influence of production parameters on the porosity, size, and shape of gelcast colloidal silica spheres. Mixtures of water, colloidal silica (10 35 wt% solids), and alginate (3 wt%) were dripped into a Ca(NO3)2 aqueous solution using needles of different diameters (0.7 1.6 mm). Their size distribution was determined using optical and scanning electron microscopy and porosity was measured by Archimedes Principle. The gelcasting technique enabled the production of spheres using colloidal particles of tunable sizes and porosity levels. Smaller beads were produced using thinner needles and lower solid contents at the same time all samples presented similar total porosity levels. Samples with 10 wt% solids showed non-uniform shrinkage, which did not allow the formation of perfect spheres after drying; those with 35 wt% showed very high viscosity and elastic behavior during extrusion, hindering the formation of beads at this concentration. Using 30 wt% solids content produced denser spheres (40 % porosity), with lower levels of shrinkage during drying, and presenting a more regular morphology and narrow diameter distribution. Such behavior was also observed reducing the needle’s diameter.

Green Synthesis of Metal-Based Nanoparticles Using Extracts from Mastic, Garlic, and Oregano.

Green synthesis is a more sustainable approach to nanoparticle synthesis as it avoids the use of toxic chemicals and reduces waste. The extracts of plants contain natural compounds that can act as reducing agents and stabilize the nanoparticles, preventing them from aggregating. This synthesis process involves mixing the plant extracts with metal salts in a solution. The reducing agents in the plant extracts convert the metal ions into metal nanoparticles, and the resulting solution is then purified and characterized to confirm the , shape, and stability of the nanoparticles. Mastic is rich in terpenes and phenolic compounds. Garlic contains sulfur compounds, flavonoids, and other bioactive compounds. Oregano contains phenolic acids and flavonoids. Using the advantages offered by the green synthesis and the mentioned extracts, the metallic nanoparticles were synthed according to Otero et. al. (2022), and later identified in this study. The morphological, structural, and optical properties were comprehensively investigated through scanning electron microscopy, infrared spectroscopy, and optical absorption techniques. The results confirmed the successful formation of nanoparticles. To further evaluate the microbial activity of the synthed nanoparticles, a series of tests were performed.Therefore,metal-based nanoparticles synthed via green synthesis using mastic, garlic, and oregano extracts have shown promising results and can be used in various applications, such as antimicrobial agents, drug delivery, and catalysis. They offer a sustainable and eco-friendly alternative to traditional chemical synthesis methods.

Hybrid Nanoplatforms based on Carbon Polymer Dotsand Halloysite

Rebecca Jemima Pereira Araujo[1], Elaine Sá Menezes Cutrim[1], Ana Clécia Santos de Alcântara[1]

[1]Universidade Federal do Maranhão

e-mail: jemima.rebecca@discente.ufma.br

Fluorescent nanomaterials have been extensively explored in recent years due to their promising applications in several fields of material science. Carbon polymer dots (CPD) show intense fluorescence emission, biocompatibility, water solubility and prominent optical properties [1], have gained significant research interest owing to their exceptional features. On the other hand, clay minerals have been identified as a promising candidate to compose versatile and multifunctional hybrid nanoplatforms for diverse applications. In this sense, Halloysite (HAL) displays unique characteristics that combine excellent mechanical properties, biocompatibility and versatile surface chemistry, being a good choice of inorganic counterpart in the elaboration of hybrid nanostructures [2]. Based on these premises, the present study aimed to develop a novel hybrid system based on CPD and the HAL clay mineral. The hybrid material was characterized by several instrumental techniques. In addition to intense blue fluorescence of the hybrid material when excited under UV light (365nm), the FTIR spectra suggested interactions between the main functional groups of CPD with halloysite surface. XRD technique revealed a slight of the peaks of HAL to low angles, which could be an indication of a possible increase of the amorphous phase in the system. In the thermal analysis from DSC, an improvement in the thermal stability of the hybrid compound was observed in comparison with the CPD alone, at the same time that these materials show interesting textural properties, which were evaluated by BET measurements. These materials can provide several applications such as attractive nanoplatforms for active molecules in drug delivery systems, optical and electronics or food sector.

e-mail: claudianaf-al@hotmail.com

The present work proposed a simplified procedure aimed at manufacturing environmentally safe, non-toxic Carbon Quantum Dots (CQDs) [1]. Despite the current worldwide expansion of nanotechnology, in the oil and gas market this area is yet incipient, although with promising perspectives. Biomass or bioresidues for the production of CQDs are alternatives to reduce the environmental and economic impacts, although these precursors are commonly misused or incorrectly discarded. Orange (Citrus sinensis) peels, for instance, areresidues composed of both soluble and insoluble carbohydrates, with high flavonoid contentand minerals, and, therefore, are excellent sources of carbon. Hence, a process to produceCQD from C. sinensis was applied via hydrothermal method, a facile, single-step and low- cost methodology, at constant temperature (180 ºC) for 8 hours, for the destination of tracerfluids in oil reservoir. A preliminary characterization of the material was performed throughcontact angle test (optical tensiometer) in carbonate rock and UV-Vis spectrophotometry, aiming to determine the stability of the CQD. The contact angle analysis, using pure dolomite rock (without petroleum), showed an angle inferior to 90º, whereas the experimentusing the oil-soaked rock the angle was higher than 90º, although this angle decreases withtime (30 min) due to the fluid-rock interaction, indicating that stone becomes wettable bythe fluid. In the UV-Vis analysis of the CQDs, only one absorption peak was observed at 272nm, which is within the expected range, and it remained stable for 8 days.

e-mail: giullianofagundes@gmail.com

The Gypsum, Calcium sulfate hemihydrate (CaSO_4 0,5H_2 O), is a material employed in constructions to make lines, plasterboards and bricks. The Pernambuco state is the biggest producer of gypsum in Brazil, and Araripe region represents 80% of the national production [1]. Gypsum ß is the type of gypsum used the most in building, considering its easy recrystallization and low cost. Although such qualities, it still need to be more studied in order to improve its mechanical properties, as its poor resistance to compression or its low hardness. Therefore, this research, utilizing gypsum ß from Araripe region, aims to provide viable solutions to that problem. First, it was characterized the gypsum slurry; then, it was produced 39 specimens to test the mechanicals characterization (hardness and compressive strength), adding three different products (A, B and C) and different ratios (5%, 10%, 20% and 30%). The test was conducted according to NBR 12.128/2019 and NBR 12.129/2019, respectively. The results show enhancement of gypsum hardness and changes in its compressive strength.

e-mail: mandsantana7328@gmail.com

This work reports the influence of co-doping on the luminescence and persistent luminescence (PersL) properties of BaAl2O4 ceramics. The samples were doped with Eu and double co-doped with different rare earths (Dy, Er, Nd, Pr, and Tm) and laser-sintered in open atmosphere at a power density of 1.6 W/mm2 . All sintered ceramics present the hexagonal BaAl2O4 phase, homogeneous microstructure. It was observed a photoluminescence emission band centered at 495 nm, which is due to the 4f6 5d1 → 4f7 Eu2+ transition in the BaAl2O4 matrix, indicating that Eu valence reduction has been achieved during laser sintering, even though the whole process was performed without atmosphere control. The PersL emission was monitored by 15 min after charging at 345 nm for 3 min. It is observed that the enhancement of the decay time and PersL intensity when the sample was double co-doped with the two best single co-dopants ions (Nd and Dy). These results suggest that the two co-dopants interact by modifying the traps configuration in the BaAl2O4 matrix being different from the simple sum of the PersL emission of the two co-dopants individually. Methodologies called Green chemistry have been highlighted in the scientific community due to the appeal for the reduction of toxic and polluting substances. In this sense, the present work aims to perform the Y2O3 particle synthesis doped with Europium ions (Eu3+), using a green route that employs aloe vera extract. Three different procedures were used to process the precursor solution: sonochemical, microwave-assisted hydrothermal,and magnetic stirring. For all methods, the Y2O3 precursor solution was prepared as follows: Y(NO3)3 and Eu (NO3)3 as reagents, and the gel extracted from aloe vera, with a 30%w in aqueous solution. The Y concentration in the precursor solution was 0.1 M, and the Eu ions were used in a concentration of 5mol% respective to the Y content. The sonochemical route and magnetic stirring were used for 6 hours at room temperature and the microwave-assisted hydrothermal route for 2 hours at 90ºC. After the initial processing,all the samples were calcined at 700ºC for 7 hours. For comparison, the synthesis of Y2O3:Eu3+ without aloe vera extract was also performed. The Y2O3:Eu3+ particles were characterized using XRD, SEM, and PL techniques. As a structural result, through all routes, the crystalline cubic Y2O3 is obtained. From the SEM analyses, it is also observed that the particles are organized in clusters of a few micrometers, which are smaller when synthed with aloe vera gel. In the luminescence, the characteristic response of the Eu3+ was noticed in the emission and excitation analyses, and interesting results for promissory application in solar cells were observed.

e-mail: davisssouza@hotmail.com

Sodium deoxycholate (NaDC) is a bile salt that above the critical micellar concentration (cmc) form aggregates spontaneously in ordered and/or disordered phases. The structure of these self-aggregates can be altered in the presence of certain molecules [1], such as cellulose nanocrystals (CNC) or nanofibrils (CNF), leading to changes in the rheological behavior of systems. It's strategic to study how CNC and CNF influence on the autoaggregation of NaDC, since there're few works that studied the aggregation of bile salts and nanocellulose [2]. Here, the rheology of NaDC (50 or 100 mM) self-assembled systems in aqueous medium was evaluated about CNC or CNF influence in the concentrations of 0.96, 2.40 and 4.80 g L^{-1}. Flow curves of all systems showed that the apparent viscosity increased with the increment of CNC or CNF concentration and presented the non-Newtonian behavior of fluids [3]. Dynamic assay in the oscillatory mode showed that NaDC 50 mM systems with CNC or CNF are much more structured and viscoelastic than CNC or CNF/NaDC 100 mM systems, since the elasticity modulus G' is greater than G" in the first case. This phenomenon suggests that NaDC 50 mM systems could possibly be gels. Also, CNF/NaDC aggregates for both surfactant concentrations were more structured and longer than CNC/NaDC systems, since G' increased. Summing up, the morphology and viscoelasticity of these self-aggregates can be altered with the proportion of nanocellulose and, mainly, of surfactant, being promising for new systems of controlled release.

e-mail: foluke.assis@marinha.mil.br

Piezoelectric materials have the capability of generating an electric potential in response to an applied mechanical stress (direct piezoelectric effect) or generating mechanical movement when subjected to an electric field (inverse piezoelectric effect) [1]. The piezoelectric ceramics are widely employed as sensors and actuators because of their idealelectromechanical properties. Their eletricmechanical properties make them suitable for use in devices such as hydrophones, static and vibration based energy harvesting devices,surgical tactile sensors, biomedical scaffolds and synthetic jet actuators [2]. Thepiezoelectric effect in polycrystalline ceramics is only obtained through the orientation of the ferroelectric domains by the temporary application of a strong electric field. This process is known as polarization [3]. In order to make the surfaces conductive, after sintering, the samples had their internal and external surfaces painted with silver paint andcured. In this article, the influence of time and temperature variation on the piezoelectric properties of PZT ceramics, for use in hydroacoustic transducers was evaluated. Currently,the following polarization parameters are used: electric field of 3kV/mm for 15 minutes atthe 100 ºC. Results indicated that the variation of time and temperature changed the piezoelectric properties, such as capacitance, electromechanical coupling and d33 parameter.

: Indium thin oxide (ITO) films are widely used as transparent conductors in various applications. In this work, tin-doped indium oxide films with different film thicknesses (305 nm, 692 nm and 1073 nm) were grown by the DC Sputtering technique. Subsequently, the as grown films were subjected to a thermal annealing treatment in a high vacuum condition. X-Ray Diffraction (XRD) data analysis revealed the formation of polycrystalline films with a bixbyite-type phase. It was determined a strong preferential orientation along the [222] direction for the thinner films. UV-Vis spectroscopy measurements indicated a transmittance value larger than 80% for the thinnest film, which decreases with the film thickness. In addition, room-temperature Hall effect measurements indicated that the increase of the electrons density leads to the transmittance decrease. It was determined high electron density values that surpass the maximum critical carrier density ($\sim 10^{19}\text{cm}^{-3}$); therefore, the electron-electron interactions become determinant and affect the optical band gap energy value. Electrical resistivity measurements carried out in the range 80-300K revealed the occurrence of a metal-insulator transition at $T\sim 113$ K. Further data analysis indicated the occurrence of quantum correlations associated with the electron-electron interactions, which show a consistent behavior determined from the optical measurements. It reveals that the electrical and optical properties of ITO films are strongly correlated, which is interesting for optoelectronic applications.

Investigating the Interaction between Quartz and Water using Molecular Dynamics Simulations with LAMMPS Software

Willian Fábio Radel[1], Marcelo Lopes Pereira Júnior[2]

[1]Universidade de Brasília (*Instituto de Física*) , [2]Universidade de Brasília (*Faculty of Technology Department of Electrical Engineering*)

e-mail: willradel@gmail.com

Quartz is a widely abundant mineral found in various types of rocks and present in all terrestrial regions [1]. It is known for its high thermal and chemical stability, as well as its hardness, making it a valuable material for a range of applications. Its interaction with water is also relevant due to its abundance in the Earth' s crust. Molecular dynamics is a branch of physics that studies the movements and interactions of molecules through modeling, simulation, and analysis. The LAMMPS software is a powerful tool for simulating atomic and molecular systems on a large scale using numerical integrators and a variety of interatomic potential models, such as Lennard-Jones potential, Morse potential, REAXFF, and the AIREBO potential. To investigate how fracture patterns affect wettability [2], thisstudy uses molecular dynamics simulations with LAMMPS. The system has periodic boundary conditions and is equilibrated with the NPT ensemble before strain is applied for100 ps to eliminate residual stresses. The system is also thermally equilibrated at ambienttemperature using the NVT ensemble for 100 ps. Strain is then applied with and withoutwater to evaluate mechanical properties, and other simulations are performed to assess thewettability. Overall, this study provides insights into the properties of quartz and its interaction with water, as well as the behavior of molecular systems using LAMMPS and theAIREBO and REAXFF potentials. The findings have implications for a range of fields, including materials science, geology, and physics.

Ion Exchange effects in Translucent Lithium MetasilicateGlass-Ceramics

Geovana Lira Santana[1], Edgar Dutra Zanotto[2,3], Oscar Peitl[1]

[1]Federal University of Sao Carlos, [2]Univerdade Federal de São Carlos (*Departamento de Engenharia de Materiais*) , [3]Federal University of Sao Carlos (*Department of Materials Engineering*)

e-mail: geovanalira@estudante.ufscar.br

Lithium silicate glass-ceramics (GCs) are the most popular materials in the field of restorative dentistry. Translucency is an important feature that affects the esthetics of dental restorations. Transparent and translucent glass-ceramics are obtained when crystallizing nano-scale crystals specially if the refractive index of the crystals is similar to the vitreous matrix. However, the presence of nano-d crystals often leads to non-interlocked microstructures that render the material susceptible to catastrophic cracking under stress. Chemical strengthening by ion exchange is employed to enhance the mechanical properties without interfering in the optical properties. The improvement of mechanical properties occurs due to residual compressive stress induced on the sample surface by replacing smaller alkali ions in the glasses (e.g., Li and Na) by larger ones from a molten salt bath (K). In this work, we developed transparent glass-ceramics with crystallization of Li2SiO3 and Li2SiO5, and investigated the effects of the microstructure and ion exchange properties. Ion-exchange treatment was conducted at different times in two molten salts containing NaNO3 and KNO3 at 380 oC and 400 oC, respectively. The ion-exchanged specimens were analyzed using X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy-dispersive X-ray spectroscopy (EDS) to investigate the microstructure and ion exchanged layer depth (DOL). The optical transmittance was evaluated using UV-VIS spectroscopy. Finally, samples were tested for flexural strength by the piston-on-three-ball method, Vickers hardness, and nano hardness. The high content of Li+ in the original glass allows for the formation of a great surface residual compressive stress. The flexural strength reached 800 ± 100 MPa (piston-on-three-ball) and Vickers Nanohardness of 11.6 ± 0.2 GPa (load of 200 mN), which are much higher than the glass-ceramic properties pre ion exchange 160 ± 50 MPa and 10.4 ± 0.2 GPa, respectively.

$La_{0.8}Sr_{0.2}Ti_{0.7}Ni_{0.3-x}Cu_xO_{3-\delta}$: Synthesis, characterization, and nanoparticles exsolution for SOFC anodes

Antonio Teofanes Bertollo Oliveira[1], Daniel Zanetti de Florio[1]

[1]Universidade Federal do ABC (*CECS*)

e-mail: oliveira.antonio@ufabc.edu.br

Climate emergency has become the century''s biggest concern due to the 1.5 ºC increase in the average temperature of the atmosphere, leading in the near future to a greater impact on natural events. In recent years, several efforts have been made to achieve net-zero emissions, based on the substitution of fossil fuels matrix by decarbonization. Solid Oxide Fuel Cell (SOFC) stands out as a viable alternative due to its high efficiency, fuel flexibility, and low-to-zero CO_2emissions. SOFC anodes are responsible for catalyzing the fuel reduction reaction. Among the used materials, perovskites are excellent candidates owing to their high mixed ionic-electronic conductivity (MIEC) and chemical and thermal capability. The present work seeks to obtain exsolved metal alloy nanoparticles anchored on perovskite structure [1] with the aim to address a more promising material, challenging and less contemplated in the literature. The nanoparticle catalysts were obtained by the interest metal solubilization into a perovskite host and exposed to a reducing H_2atmosphere. The $La_{0.8}Sr_{0.2}Ti_{0.7}Ni_{0.3-x}Cu_xO_{3-\delta}$(x = 0.1, 0.15, 0.2) powders were obtained by the Pechini synthesis route and calcined at 900 °C for 5 hours. To obtain decorated NiCu nanoparticles alloys, the powders were heat-treated under 3 vol % H_2/N_2atm at 900 ºC, 850 °C, 800 °C and 750 °C for10 hours. The samples were characterized by scanning electron microscope, X-ray diffraction, X-ray photoelectron spectroscopy, and electrochemical impedance spectroscopy. Rietveld refinement was used to determine structural parameters such as crystal symmetry, crystallite size, strain, and phase content before and after reduction treatment. The preliminary results revealed that the chosen synthesis route and the reduction treatment were successful in obtaining NiCu nanoparticles alloy.

e-mail: vivianemazur@utfpr.edu.br

The installation of solar panels in external environments invariably leads to the accumulation of dirt on its glass surface, such as industrial or vehicular soot, salinity, sand, dust, organic materials, among others. As a result, efficiency reduction is observed, since the free light passage through the glass is compromised. In this work, CAD technology and 3D printing were used to develop a device to quantify the obstruction of the light passage in glass slides. Commercially available components were used, including Arduino, a luminous density sensor, a 1 W solar panel and an LED board to compose the prototype. The functionality of the device was demonstrated by quantifying the light passage and generated voltage after exposing glass slides samples to different external environments, for 30 days. The research results showed that it is possible to simulate the dirt accumulation on the solar panels glass surface, and based on this, maintenance cleaning can be schedule to avoid significant efficiency losses.

Light Emitting Diodes (LEDs) have revolutionized modern lighting due to their high luminous efficiency and less environmental impact. However, traditional LEDs are dependent on rare earth ions, which have high cost and nonrenewable resources [1]. In recent years, carbon dots (CDs) have been highlighted as new luminescent materials for making LEDs rare-earth-free. In this work, CDs were synthed from banana peel **(B-CDs)**and neutral red with citric acid **(Nr-CDs)**for luminescence modulation to generate a fluorescent film and apply as an outer layer in LEDs to improve the electrical properties. In this sense, **B-CDs**and **Nr-CDs**were embedded in the polymer (PVA; poly (vinyl alcohol)) to obtain the film **(BNr-CDs-F)**. All CDs exhibited absorption bands related to π → π* and n → π* characteristic of the graphitic structure and surface functional groups, respectively.[2]**B-CDs**showed excitation-wavelength-dependent emission with maximum intensity at 454 nm (λ_{exc}= 360 nm). On the other hand, **Nr-CDs**displayed intriguing dual-emission behavior at 450 and 600 nm. In addition, **Nr-CDs**and emission modulation of both CDs (**B-CDs**and**Nr-CDs**) exhibited fluorescence close to the CIE chromaticity coordinates (x,y) for pure white light emission (0.33, 0.33). **BNr-CDs-F**film was applied as an outer layer on the UV LED (λ_{exc}= 200 nm, 50 cd.m^{-2}). Except for the B-CDs film, the use of the **Nr-CDs**and **BNr-CDs-F**films amplified the efficiency of the commercial LED around 2 (109 cd.m^{-2}) and 7 times (374 cd.m^{-2}), respectively. Furthermore, different white color variations were obtained by changing the power of the LED. Finally, the results obtained indicated that the outer layer produced by modulating the fluorescence of the CDs was efficient to increase the efficiency of commercial LED.

e-mail: naiarasantos.ufs@gmail.com

Materials produced via eco-friendly routes has been highlighted in recent years [1]. In this work, the modified sol-gel route using organic matter from river water was used to produce nanomaterials. The material of interest is yttrium oxide (Y2O3) undoped, doped, and co-doped with europium and terbium ions. Y2O3 is considered a great host matrix for rare-earth ions to improve their luminescent properties, consequently, it can be used in the manufacture of lasers, sensors, solar cells, among others. The samples were calcined at a fixed temperature of 1000 ºC, and the parameters investigated in the initial part of the work were the doping concentration and the reproducibility of the synthesis by using river water from different origins. The explored concentrations were: 1%, 2% and 5%. Powder XRD measurements, showed that single crystalline phase were obtained for all samples regardless of the origin of the river water, which indicates good reproducibility of the Y2O3. Furthermore, when estimating the average crystallite of the sample produced with distilled water and river water, 26 nm and 31 nm were obtained, respectively. The diffraction patterns of the doped samples did not show secondary peaks, which implies that the doping was successfully performed. Photoluminescence measurements were performed, and the emission spectrum presents the characteristic peaks of Eu and Tb. For the excitation spectrum, several bands from 170 up to 466 nm were observed, making this material a potential candidate for many applications, such as solar cells and luminescence thermometers.

e-mail: valeria.maia@academico.ufpb.br

Reinforcing fibers in concrete structures have been successfully applied due to their superior mechanical properties and anchoring capacity. In the case of synthetic polymers [1], nylon 66 (polyamide 66, PA66) is a multifunctional synthetic thermoplastic polymer, being tested today for use as reinforcement in cementitious composite engineering with good cost-benefit results. In this field, the fibers can act on the cracked surface as a bridgeeffect, providing residual tensile strength [2]. Furthermore, with the use of nanostructuredfibers, new properties emerge due to the high surface area, the elongated length and the high degree of entanglement. For the rapid fabrication of nylon 66 fiber materials, solutionblow spinning (SBS) technique [3] was used, which has a high efficiency and low cost. Thefibers were characterized by Scanning Electron Microscopy (SEM) and Fourier TransformInfrared Spectroscopy (FTIR) and dispersed in a cementitious matrix. SEM results showedfiber morphology obtained and FTIR showed strong hydrogen bonding interaction. The compressive strength of concrete was higher in samples with micrometric nylon fibers. Finally, tests indicate that the use of SBS enabled the production of nylon 66 fibers quickly and efficiently, which can be used as suitable choices to produce cementitious composites with acceptable performance and low prices for usual applications in the construction industry.

e-mail: pfilipeacq@gmail.com

Hierarchical zeolites are a class of materials that exhibit unique properties due to their porous nature, which allows for the selective adsorption and catalysis of molecules [1]. The ZSM-5 zeolite is one of the most widely studied due to its high acidity and shape-selective catalysis [2]. The goal of this work is to develop hierarchical zeolites from mechanical activation of NH4ZSM-5 (Si/Al=23) using two templates: tetrapropylammonium bromide (TPA) and cethyltrimethylammonium (CTMA) in the absence of solvents. The reactants were mixed in a ball mill (IKA instruments, Ultra Turrax Tube Drive UTTD), and milled varying the time from 0 to 20 min. The calcined materials at 550 oC were analyzed by X-ray diffraction (XRD), infrared spectroscopy (FTIR) and scanning electron microscopy (SEM). The XRD showed well defined pattern for MFI structure, indicating that there was no amorphization under the mechanical treatment. This was confirmed by the SEM and FTIR. The ZSM-5 activated by 10 and 15 min exhibit a small increase of the crystallite , calculated by the Scherrer equation, whereas for 5 min was observed a loss in crystallite , suggesting that the treatment at this time is enough to break the siloxane bond (Si-O) and create space for the TPA and CTMA fill the pores generated through the ball milling. At times higher than5 minutes, is proposed a breaking of Si-O-Si bonds followed by recrystallization and possible increase of the of crystallite over the time.

e-mail: bruna.sa@unesp.br

Carbon structures are widely studied mainly due to their electronic properties, which allow their application in supercapacitors, energy harvesting, sensors, and other electronic devices. The possibility of preparing these materials from methane gas makes the idea even more interesting. Furthermore, carbon structures can be formed on different substrates, such ceramic fiber paper (CFP). This substrate is flexible, chemically stable and withstands high temperatures (~1,200 °C) [1]. Thus, in this work, we synthed carbon structures from methane on CFP by the chemical vapor deposition (CVD) method. The CVD was performed in a sample of CuO impregnated CFP. To produce the CFP-CuO sample, pieces of CFP were quickly immersed in an alcoholic solution of copper salt and dried in an oven. After that, the sample was calcined to form the CuO phase. Then, a tubular oven with nitrogen and methane gas flow was used to perform the CVD method [2]. The CFP-CuO sample was inserted into the tubular oven, the nitrogen gas flow was used to clean the atmosphere inside the tube. The oven was heated to and the methane gas flow was opened for 10 min. After that, the methane gas flow and the heating were stopped. The nitrogen gas was used to clean the tubular oven again and the sample was recovered at room temperature. The samples were characterized by X-ray diffractometry (XRD) and scanning electron microscopy (SEM). The XRD confirmed the formation of CuO and carbon on the samples. The SEM images showed that carbon nanotubes grew on the CFP-CuO.

Microscopic electrical conduction in carbon-black materials

José Arruda de Oliveira Freire[1], Alex Aparecido Ferreira[1]

[1]Universidade Federal do Paraná (*Física*)

e-mail: jfreire1967@gmail.com

The electrical properties of carbon-blacks materials have been intensively studied. This powder material is largely used in composites, pigments, coating applicatins, UV shielding, and etc. Carbon-blacks are made of nearly spherical carbon nanoparticles fused into chain-like structures called aggregates. Therefore, the electron conduction should depend on the capacitance between neighbor aggregates. In this work we have modeled the aggregates with defined fractal dimension, the inter-aggregate capacitance and the space distribution of the path channels used by an conduction charge. Our results will be useful to better explain the electron conductivity in carbon-black samples.

Microstructural evolution of castable high-alumina ceramics bonded with anionic colloidal silica

e-mail: ana.figueiredo.prado@usp.br

Ceramic materials based on mullite (Al6Si2013) are used in high-temperature-based industrial processes due to resistance to corrosion and refractoriness. In this work, samples of alumina-mullite were produced from a dispersion of anionic colloidal silica and calcined alumina particles processed by the direct casting method and treated isothermally in the 120-1500°C temperature range. Samples were submitted to non-destructive tests for evaluating the physical, chemical and microstructural properties. The drying behavior established parameters that ensure a sufficient level of mechanical strength to hand green samples. After drying, CS-bonded samples presented higher elastic modulus than the calcium aluminate cement and hydratable alumina-bonded ones, tested as references under the same conditions. Increasing isothermal treatments' temperatures, the stiffness modulushas increased, differently from the behavior shown by the other binders. Crystalline phasesrelated to cristobalite and mullite formation were detected above 900°C. Regarding the microstructures, the dry samples showed superficial microcracks. Although they grew with the increase in the firing temperature, they did not compromise the mechanical properties of the parts.

Modeling emissions by rate equations and evaluating relative thermal sensitivity of a ytterbium-erbium codoped nanoparticle system

Wagner Ferreira da Silva[1], Roberto Constantino da Silva[1], Carlos Jacinto[2]

[1]Universidade Federal de Alagoas (*Instituto de Física*) , [2]Universidade Federal de Alagoas (*Física*)

e-mail: wagner@fis.ufal.br

Temperature is a crucial parameter across a wide range of phenomena and fields, including physics, biology, medicine, and more [1]. Specifically, in nanomedicine, temperature plays a significant role in both diagnostic and therapeutic applications, both in vitro and in vivo [2]. For instance, real-time temperature monitoring is critical in preventing healthy tissue overheating during photothermal therapy [3]. Motivated by these and other factors, our objective was to use rate equations to model the emissions of a system (LaF3 nanoparticle) codoped with 18 wt% of Ytterbium and 2 wt% of Erbium ions, both trivalent. The simulations were performed using the Octave software. As a result, we found that the analyzed emissions showed a behavior in excellent agreement with those obtained in experiments. Furthermore, we evaluated the relative thermal sensitivity of the system by analyzing the fluorescence intensity ratio (FIR) between the emissions at 520 and 540 nm. A maximum relative thermal sensitivity of 0.14%/K at 425 K was obtained, which is consistent with values reported in the literature.

Morphology tailoring of oxide particles by gas pressure hydrothermal synthesis

Armando Monte Mendes[1], Antonio Eduardo Martinelli[2], Sibele Berenice Castellã Pergher[3], Rafael Chaves Lima[3]

[1]Universidade Federal do Rio Grande do Norte (*Engenharia de Materiais*) , [2]Universidade Federal do Rio Grande do Norte (*ENGENHARIA DE MATERIAIS*) , [3]Universidade Federal do Rio Grande do Norte

e-mail: armandomonte@gmail.com

The properties of oxide particles are directly related to their morphologies [1]. This work presents a new adaptation of the hydrothermal synthesis method, which can promote morphological changes in the synthed materials (ZnO and Mordenite) by the injection of pressurized inert gas [2]. ZnO particles were synthed at 120°C for 20 h and pressures of 1.4bar (autogenous) and 50 bar (argon), while mordenite was processed at 170°C for 20 h and pressures of 6.5 bar (autogenous) and 25 bar (argon). SEM and XRD analyses showed that both materials underwent significant changes in their morphologies, different from those achieved under normal synthesis conditions (autogenous pressure), while their crystalline aspects remained unchanged.

Nanoreactor approach in the preparation of carbon nanoparticles

Volodymyr Zaitsev[1], Albina Mikhraliieva[2]

[1]Pontifícia Universidade Católica do Rio de Janeiro (*QUIMICA*) , [2]Pontifícia UniversidadeCatólica do Rio de Janeiro (*Chemisty*)

e-mail: vnzaitsev@puc-rio.br

The conventional synthesis of carbon nanoparticles (CNPs) is low-temperature pyrolysis of individual organic compounds under solvothermal or microwave-assisted treatment. Due to different carbon sources and synthetic conditions, CNPs commonly have different sizes, surface chemical composition, and photoluminescent properties. Thus, these approaches are unable to ensure the reproducibility of the synthesis. The primary strategy to improve synthetic conditions is spatial isolation of the carbon sources in nanoreactors. The confined space of nanoreactors can increase the probability of reaction collision and the mass transfer of reactive chemical molecules, thereby significantly improving the efficiency of chemical reactions. The current presentation will discuss various methods used for spatial isolation of the precursors in CNDs synthesis. The preparation of CNDs using vesicles and micelles is one of the nanoreactor strategies. It was demonstrated that sugar carbonization inside reverse micelles built from bis(2-ethylhexyl) sulfosuccinate resulted in fluorescent CNDs with 1.8–4.0 nm in size. Fatty acids were used as amphiphilic nanoreactors obtainingin situ upon irradiation (Xe lamp 500 W 4–12 h). When nonanoic acid was used as a carbonsource, CNDs with particle size 1.6 nm were obtained despite the vehicle''s large size (100nm). Another example of the nanoreactor approach is the utilization of mesoporous metal–organic frameworks (MOFs). Depending on MOFs'' cave size, CNDs with sizes of 1.5, 2.0, and 3.3 nm can be obtained from glucose. Several attempts to use molecular sieves and other microporous materials as templates for CNDs synthesis were also described. In most cases, there were essential contradictions between the size of the pores of the template and the size of the carbon particles received. The application of mesoporous materials to confine the growth and shape of carbon nanoparticles and their aggregation is rapidly developed in recent years.

Nanostructures of CuO and CuO/ZnO in the Productionof Biodiesel from Residual Cooking Oil

Philip Alexandre Araújo Ventura dos Santos[1], Joelda Dantas[1], Elvia Leal[2], Ana Cristina Figueiredo de Melo Costa[2], Marta Célia Dantas Silva[1]

[1]Federal University of Paraíba (*Centro de Energias Alternativas e Renováveis*) , [2]Universidade Federal de Campina Grande (*Unidade Acadêmica de Engenharia de Materiais*)

e-mail: philip.santos@cear.ufpb.br

Biodiesel is a biofuel that could replace fossil diesel. It is extracted from biomass which is considered a renewable source of energy, therefore it is a clean fuel. Biodiesel production is practiced at a global level, and Brazil has the advantage of its great energy potential for this purpose. Oilseeds, animal fats and residual oils from frying are used as raw materials. This potential also extends to the research and development of catalysts that contribute to improve yields and increase the speed of chemical reactions in the production of biodiesel. Among these, esterification is used to obtain alkyl esters, better known as biodiesel. Thus, this work aimed to initially use 100% CuO and 80% CuO catalysts with the addition of 20% ZnO as test parameters to produce biodiesel from residual cooking oil. The catalysts were synthed through the combustion reaction and were characterized by X-ray diffraction (XRD), infrared spectroscopy (FTIR) and thermogravimetric analysis (TG). After the characterization of the catalysts, the esterification reaction of the residual frying oil was carried out, aiming at its conversion into biodiesel. Finally, the efficiency of the catalysts was verified by the analysis of gas chromatography, which obtained a result of conversion of residual oil into biodiesel of 17.95% for CuO and 80.4% for CuO80/ZnO20. The results of the structural and thermal characterizations revealed that the metallic oxides used as catalysts have suitable properties for application in the production of biodiesel, which achieves greater sustainability as a result of the recovery through the use of residual biomass offered in this work.

Ni nanostructures formed by pH-dependent corrosion-redeposition of thin nickel films using glycine solutions

Ayron Andrey da Silva Lima[1], Duber Marcel Murillo Munar[1], Antonio Augusto G. von Zuben[1], Monica Alonso Cotta[1]

[1]Gleb Wataghin Physics Institute, University of Campinas (*Department of Applied Physics*)

e-mail: ayron645@ifi.unicamp.br

Properties such as resistance to high temperatures, oxidation and corrosion make nickel (Ni) an interesting material for many applications, which include Ni nanostructures. For example, applications of Ni nanowires range from optical devices and solar cells to sensors and biotechnology. Several methods have been used so far for the synthesis of Ni nanostructures, such as hydrothermal, laser ablation and chemical vapor deposition [1,2]. In this work, we explore a different method for the synthesis of Ni nanostructures, based on local corrosion of thin Ni films prepared by physical vapor deposition. We demonstrate and explore the slow Ni corrosion produced by solutions containing water, glycine and calcium chloride, with different pH values. After a relatively long (48h) contact time between Ni film and solution, we observe isotropic corrosion patterns with approximately circular shapes. Within the surface patterns, nanostructures are formed; usually a nanowire-like structure projects vertically from the center of most patter for the larger patterns, very thin planar nanowires, with a fractal aspect, originate from the structure at the center. Energy Dispersive Spectroscopy measurements carried out with Scanning Electron Microscopy shows that the central nanostructure is composed of Ni, while the composition of the thinner, planar nanowires can not be resolved. Our results point to a process of corrosion at local defects of the film, and redeposition due to the radial gradient of Ni dissolved in the solution, which is kept static during the whole time. Further studies can determine if this process can be made controllable as a new synthesis process of Ni nanostructures.

Graphene is a two-dimensional material composed solely of carbon atoms bonded in a hexagonal structure. Its unique properties, such as high electrical conductivity and rigidity, make it a material of great interest in scientific research. Nevertheless, some applications still require tailor specific properties. One interesting approach to this end is doping graphene with atoms of other substances, such as nitrogen, which can further improve its properties, making it even more versatile in terms of applications. However, the nitrogen doping process can weaken the graphene sheet since carbon-nitrogen bonds are weaker than carbon-carbon bonds. Also, excessive doping can lead to material rupture, rendering it unusable. In this context, this work applies molecular dynamics simulations to investigate the effects of nitrogen-doped graphene on mechanical and topological properties with different doping percentages (1 to 4%), temperatures (100 to 900 K) and defects (0.05 to 0.4%). The graphene sheet was doped with nitrogen by replacing randomly carbon atoms with nitrogen atoms, while defects were inserted by randomly removing carbon atoms using a 17nm x 17nm structure containing 11200 particles. The results showed that the doping of graphene with nitrogen decreases the material's strength by approximately 14% compared to pristine configuration. However, it was not observed a significant difference in mechanical resistance with the doping level. As expected, the increase in temperature and defects also decreases the doped graphene's strength, reaching a maximum reduction of around 28% and 32%, respectively. Finally, all studied configurations remained stable during the mechanical testing, demonstrating that they might be suitable for further experimental analysis.

The synthesis of zeolites materials containing metals such as Al, Y, V, Sn, Nd, Nb and Zr in octahedral;pentahedral;tetrahedral coordination (OPT' s) composing the crystal lattice of the material, received increasing attention over the years [1-2]. In this work, different hierarchical zeolites containiung transition metal based materials are reported. The syntheses of these materials were adapted from earlier reports described elsewhere [3]. The use of tetra propyl ammonium bromide (TPABr) known as a structure-directing agent (SDA); Bismuth (III) nitrate pentahydrate (Bi(NO3)3.5H2O), V2(SO4)3 and $SnCl_2$. $2H_2O$ as metal source Ludox HS-30 colloidal solution as a source of silica (SiO2) and pellets of sodium hydroxide (NaOH) as a mineralizing agent, were utilized to produce the material. The materials were silanized utilizing APTES and APTMS, and functionalized afterwards with glutaraldehyde to immobilize the laccases from Trametes villosa and Pycnoporous sp. To removal of textile dyes by adsorption and biodegration [4]. The results obtained suggested that the application of a new and hierarchical material containing bismuth in its framework as a physical support was successful, being possible to retain the enzyme in this material and to apply as removal agent of the dyes in aqueous solution. Bioinformatics studies was conducted to help us understand the mechanism of how laccases interact with the hierarchically structured supports, allowing to make an optimization of the immobilization process and the immobilized enzyme activity.

The study of systems formed by surfactants has been increasing in recent years, the great interest in these types of structures is due to their broad biochemical and biomedical potential. The mixture of surfactants can lead to the formation of different aggregates, such as wormlike micelles, reverse micelles, liposomes and vesicles [1]. The bile salts, such as sodium cholate, are natural amphiphilic surfactants, stored in the gallbladder, and act to emulsify and lipids to facilitate digestion [2]. Lecithin is a phospholipid, a naturally occurring zwitterionic surfactant, found in egg yolks and soybeans, and can form reverse wormlike micelles when incorporated into other molecules [3]. Sodium cholate/lecithin systems were prepared in different ratios (0.2; 0.4 and 0.8 (m/m)). They were also prepared with two solutes: polyethylene oxide or propylene glycol, to verify changes in the arrangement and dimension of aggregates. In this sense, the and shape of the aggregates were determined by Dynamic light scattering (DLS), small angle X-ray scattering (SAXS) and rheology studies were performed to determine the parameters such as relaxation time, modulus at the plateau, elastic modulus, viscous modulus and frequency.

e-mail: helder@ufscar.br

Extensive work on InAs quantum dots grown on GaAs substrates has been reported in the literature. However, research in the use of different substrate materials such as silicon to achieve an ideal and full integration of photonic and electronic systems is still a challenge. In this work we have investigated the effect of the substrate material (Si and GaAs) and strain reducing layer on the optical properties of InAs quantum dots for possible applications in laser devices grown by Molecular Beam Epitaxy. Two InAs quantum dots structures with similar active regions grown on GaAs and Si substrates using strain reducing layer consisting of InAs QDs/6 nm $In_{0.15}Ga_{0.85}As$ have been investigated. Atomic Force Microscopy, Transmission Electron Microscopy, and photoluminescence have been used for the characterization of the samples. We have observed a red shift of the InAs QD photoluminescence peak energy for the sample grown on Si substrate as compared to the sample grown on GaAs substrate, which was associated with residual biaxial strain from the Si/GaAs heterointerface. The red-shift of the photoluminescence peak energy is accompanied by a broadening of the photoluminescence spectrum from ~31 meV to a value of ~46 meV. This broadening is attributed to the quantum dots inhomogeneity increase for samples grown on Si substrate. This result open new insights for the controlling the emission of InAs quantum dots for photonic device integration using Si substrates.

The work has been supported by Fundação de Amparo a Pesquisa do Estado de São Paulo (FAPESP) (grants no. 19/23488-5 and 19/07442-5), Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq)

Physical and microstructural characterization of recycled aggregate obtained from geopolymer concrete

e-mail: g1ovannafranca022@gmail.com

Geopolymers are inorganic materials composed of a source of aluminosilicates together with an alkaline solution, and have high adhesion due to their rheology and structure when applied as a matrix in concrete and mortar [1], [2]. The recycling of concrete as an aggregate is the subject of studies due to the incorrect disposal of the second most produced artificial material in the world [3]. In the present study, the density, water absorption, and microstructure of aggregates produced from geopolymeric concrete were evaluated. The geopolymer concrete was fragmented, sieved and segregated to obtain the gravel granulometry 0, above 4.75 mm. After this process, the aggregates were submitted to physical tests of water absorption and density, and analyzed by optical microscopy. The aggregate showed a high water absorption, about 17%, and the density was about 5,165 kg/m3, and the microstructure showed low adhesion of the aggregate already present in the aggregate coming from the concrete, which causes a low resistance.

e-mail: lee.marx@ufpi.edu.br

Kaolinite, a naturally occurring mineral clay with chemical formula $Al_2[Si_2O_5](OH)_4$, with good availability and low cost, is widely used in industry as an additive for polymeric compounds, filler and coating for ceramic materials [1]. Kaolinite shows high porosity, high adsorption capacity and plenty of hydroxyl groups capable of participating in many chemical reactions, as well as ionic exchange processes. Such properties qualify this mineral clay as a good adsorbent for removing pollutants (dyes, for example) from wastewater [2]. The lack of studies on the application of kaolinite (available in the Picos microregion, specifically in the municipality of Oeiras, in the state of Piauí-Brazil) to studies of environmental remediation,as adsorbent, became an attractive and a relevant issue. So, it is important to understandthe physicochemical properties of kaolinite from that region. Using characterization techniques, such as XRD, FRX, FTIR, SEM, BET, TG and Zeta potential, one can evaluate the chemical and physical structures as well as the morphology and compare them with the data from literature. Considering the results in initial adsorption tests of methylene blue (as a model dye) on powders of kaolinite from Piauí-Brazil, it can be concluded that this materialis very promising.

e-mail: vivicamaia@hotmail.com

Polymers such as high-density polyethylene (HDPE) and polyethylene terephthalate (PET) are widely used, generating large amounts of post-consumer waste($_{PC}$)[1], requiring conscious innovations in raw materials, products and technologies [2] .The objective of this work was to produce HDPE/PET$_{PC}$polymeric blends, for the company COGUMELO, which currently only recycles HDPE$_{PC}$. Were extruded 6 blends$_{PC}$: A1.1-60HDPE/40PETCR, A1.2-60HDPE/40PETIG, A2.1-70HDPE/30PETCR, A2.2-70HDPE/30PETIG, M1.1-50HDPE/50PETCR, M1.2-50HDPE/50PETIG and PEAD$_{PC}$(range 140-240 ºC and 140-150 RPM) for the production of specimens in a heated hydraulic press (thermal analysis: HDT and VICAT) and injection in a closed mold (COGUMELO mechanical test - Deflection: 900mm clearance). Results obtained for HDT(℃)-HDPEPC:66.6, A1.1:75.6, A1.2:79.8, A2.1:73.3, A2.2:75.4, M1.1:77.0, M1.2:87.0;VICAT(℃)-HDPEPC:110.5, A1.1:116.1, A1.2:119.7, A2.1:119.1, A2.2:117.8, M1.1:124.6, M1.2:123.6 and Deflection (mm)-HDPE$_{PC}$: 3.94, A1.1:3.03, A1.2:2.84, A2.1:3.09, A2.2:3.44, M1.1:2.31, M1.2:2.05. The incorporation of PET$_{PC}$in the blends promoted an increase in the values of thermal and mechanical resistance, compared to the values of the HDPE$_{PC}$matrix, provided by the benzene group responsible for the stiffness of the PET chain, giving the material greater thermal and mechanical resistance in the solid state[3].Acknowledgements: FAPERJ, COGUMELO, UERJ-ZO.References:[1] ITO,E.N.;BALABAN, R.C.Comportamento Mecânico de compósitos a base de blenda de PET reciclado/PEAD reforçados com fibras de bananeira roxa.1ªed.São Carlos:Associação Brasileira de Polímeros Regional Nordeste, 2014, v.1, p.45-48.[2]ABIPLAST.Associação Brasileira da Indústria do Plástico, 2019. e-mail: nivialcsiqueira@gmail.com

Scheelite, or calcium tungstate ($CaWO_4$), is a mineral which represents great economic importance for responding to one of the largest quantities of tungsten production, being widely found in the Seridó region of Rio Grande do Norte, Brazil [1]. In recent years, Tungsten-based materials have gained attention of the industry due to their unique physical-chemical properties and their excellent electrochemical performance, being often used as components of energy storage and saving devices [2]. Parallel, the tape casting method is a well-established method to produce thin and flexible sheets, often applied in electronic industry [3]. Therefore, the aim of this research is to produce Scheelite sheets by aqueous tape casting and to evaluate the dielectric properties and applications. The Scheelite powder was obtained in Brejuí Mine, and characterized by X-ray fluorescence and diffraction analysis. The rheologic behavior of the suspension was measured, in addition to the dielectric properties of the sheets. SEM and EDS analysis were performed to evaluate the characteristics and composition of the surface of the sheets. The obtained results satisfied the expectations for the desired applications.

Production of silicon carbide (SiC) using rice husk and microwave radiation

Beatriz Santos Assunção[1], Guilherme Frederico Bernardo Lenz e Silva[1]

[1]Universidade de São Paulo (*Engenharia Metalúrgica e de Materiais*)

e-mail: beatriz_assuncao@usp.br

The production of silicon carbide is known for using a high temperature process, known as the Acheson process. An alternative route that has been studied is a synthesis using microwave radiation, where the mechanical waves generated by the frequency of 2.45 GHz are capable of propagating heat through phonons. Studies based on microwave-assisted synthesis are promising and more economical than the previous one. [1]. The rice husk is a product of the production of rice and is abundant in all of the rice producing countries and is generally treated as a waste. In its composition, there are 50% of organic carbon and 15% to 20% of SiO_2[2]. After the carbonization process of the rice husk, the ashes generated contain around 90% of SiO_2[3]. The aim of this project is to produce SiC from rice husk provided by a rice mill in the south of Brazil. The raw material was milled and characterized using X-ray fluorescence spectroscopy (XRF), Scanning electron microscopy (SEM) and Thermogravimetric analysis (TGA). The characterized rice husk was carbonized after the milling processes in a furnace at temperature of 600ºC for 3h and the material obtained was 41,6% of SiO_2. This same material was submitted in a loss of ignition analysis at a temperature of 1.000ºC for 5h. This material had 55% of its mass of loss in ignition material and the ashes remaining were about 85% of SiO_2. The results confirmed the percentage of SiO_2 obtained in previous studies.

e-mail: maria.elayne@ufpi.edu.br

The sustainable development of materials for environmental remediation with applications in agriculture has aroused interest. For example, the recovery of phosphorus (P) from sludge for use as fertilizer. Attapulgite, a hydrated magnesium clay mineral abundant in thestate of Piauí, is effective as a P adsorbent material, by several mechanisms, due to its chemical composition and morphology [1]. Initially, the attapulgite was characterized by XRD, where peaks characteristic of this mineral was observed in the region of 8.46° and 20.21°, by FRX highlighting the percentages of 38.51% of SiO_2, 9.15% of MgO, and 15.49% of CaO and by SEM, where a fibrous morphology is observed. In addition, the methodologyfor recovering the P in the sludge is imperative, focused only on the removal andimmobilization of this nutrient in its various forms. In this context, the hydrothermal treatment proved to be effective in improving the bioavailability of P in the sludge and improving the properties of attapulgite in isolation until then [1],[2]. Therefore, their jointuse is justified as a viable alternative due to their effects on the adsorption/desorption of P from sludge by attapulgite for fertilizer in agriculture.

e-mail: matheusribeirods@hotmail.com

With the prospective study of advanced materials in optical properties, it is concluded that advanced ceramics is an area with great potential and that has been standing out due to its use in optical applications. Advanced ceramics is a material of great importance in the development of optical devices, being used in several photocatalytic applications. This is an area that presents a high versatility presenting materials with high performance. The objective of this work is to carry out a prospective study of advanced materials, focusing on advanced ceramics, analyzing their optical properties, and thereby identifying trends in research and development, as well as the most relevant companies and research institutions in the area. Based on this, several methods of analysis of literature and articles will be used, including citation search, keyword competition, patent search and collaboration networks. Seeking to identify the main optical properties of advanced ceramics, such as radiation detection. From the analysis of the collected data, it is expected to identify trends in research and development of advanced ceramics focused on the optical part of the material. Based on the results obtained, opportunities for new research and technological developments and the application of advanced ceramics in optical devices in different sectors can be identified. Thus, the prospective study of advanced materials in optical properties is an important and constantly evolving research area, with great potential to contribute to the development of new technologies and optical applications.

Red fluorescent of quantum dots ZnS:Mn powder for visualization of latent fingerprint

Anderson Selton Silva dos Santos[1], Islaine Elí Lima Gomes[2,3], Rodrigo da Silva Viana[4], André Lopes Ruiz Talhari[5], Cintya D'Angeles do Espírito Santo Barbosa[6,3]

e-mail: andersonselton@gmail.com

The development of latent fingerprints at crime scenes have been an important step in criminal investigation and forensic science [1]. Fluorescent materials for revealing latent fingerprints (LFP) have increased due to high contrast on several surfaces, sensitivity, and selectivity [2]. In this sense, heavy-metal-free quantum dots (QDs) chemical passivated with polyvinylpyrrolidone (ZnS: Mn/PVP) were synthed via a simple route at room temperature a low-cost to obtain a high luminescence alternative platform for revealing LFP. These revelations have been assayed on four surfaces: glass, ceramic, plastic, and synthetic leather. X-ray powder diffraction (XRD) investigation showed characteristic planes for ZnS structure (cubic crystalline system; space group F-43m) corresponding to the crystallographic data described by Ebnelwaled et al [3]. FTIR spectra for ZnS:Mn revealed a band between 473-535 cm^{-1}related to Mn-O interaction, a signal at 1003 cm^{-1}corresponds to the stretching of the S-O-C bond and stretching of the C-S bond centered at 655 cm^{-1}. Mn^{2+} doped ZnS QDots optical properties exhibited an absorption maximum at 250 nm, witha band gap energy value of 3.13 eV. In addition, ZnS: Mn QDs showed a photoluminescencein the red region with a broad band centered at 590 nm. ZnS: Mn QDs were effective in developing LFP under UV light on different surfaces, being able to identify the pattern of fresh fingerprints developed. Furthermore, the developed images were compared with the control sample, a standard forensic software, and showed an excellent match, suggesting that ZnS:Mn QDs may works a promising low-cost fluorescent powder candidate for forensic applications.

e-mail: CLP@QUI.UFAL.BR

Concentrations of NO_3^-in groundwater have been increasing, due to the increased agricultural and industrial activity [1]. Due to the high solubility and stability, this ion has a low tendency to be removed by using conventional water treatment technologies such as adsorption. The present work aimed to evaluate the possibility to increase the efficiency of the adsorption process of a commercial biocarbon (C) by the acidic and basic activation. Initially, the C activation test was carried out with 0.5M NaOH and 0.5M H_2SO_4solutions, followed by washing, filtration and drying. Then, affinity tests with activated carbon (AC) were performed using 0.5g of AC in 50 mL of a 50ppm NO_3^-solution. AC affinity studies were performed as a function of the nitrate solution pH (pH 2, 4, 6, 8 and 10). For AC with NaOH no nitrate removal was observed for pH 4, 6, 8 and 10, whereas for pH 2, 83.4% of nitrate was removed. For AC with H_2SO_4, removal of 97.6, 48.9, 21.90, 20.70 and 6.15% were obtained for pH 2, 4, 6, 8 and 10, respectively. The greater efficiency of adsorption in acidic pH of the nitrate solution, mainly in pH 2, is due to the protonation of the active sites of the AC that favor the adsorption of the ionic species NO_3^-. Expanding study, the C activations were carried out with solutions of 0.1, 0.5, 1.0, 2.0, 3.0 and 4.0M H_2SO_4. In the affinity tests with nitrate solution in pH 6,0 were removed 40.4, 41.6, 50.7, 53.0, 55.7, 88.6% of nitrate for AC with solutions 0.1, 0.5, 1.0, 2.0, 3.0 and 4,0M H_2SO_4, respectively. Second Afkhami et al. [2], the treatment of C with H_2SO_4tends to produce positive sites on the C by protonation of surface -OH groups that would cause an increase in electrostatic adsorption of anions ($S\text{-}OH + H^+ \boxed{\leftrightarrow} S\text{-}OH_2^+ / S\text{-}OH_2^+ + X^- \leftrightarrow S\text{-}OH_2X$).

The demand for energy from renewable and sustainable sources is rapidly growing worldwide. In Brazil, hydroelectric energy is the most used source. However, due to the seasonal availability of water resources in some regions, shared use of solar power plants isa viable alternative, both technically and economically. A problem associated with this technology is the high demand for photovoltaic modules and the waste generated during their operation and after their estimated 25-year lifespan, which can reach masses exceeding 50 million tons. Specifically, glass and semiconductor elements can be used in the development of geopolymeric products, partially replacing Portland cement, using aluminosilicate in an alkaline environment. Thus, this investigation aimed to reuse glass and semiconductor material to generate a geopolymer based on metakaolin. The glass and silicon cells were obtained from damaged solar panels during the installation process of the FloatPV SC solar power plant, located in the reservoir of the Santa Clara hydroelectric plant, in the state of Paraná, Brazil. In this case study, damaged photovoltaic panels from silicon polycrystalline photovoltaic modules were used for their mechanical separation. Experimentally, the glass, EVA, and semiconductor material were crushed together in a jaw-type equipment and subsequently milled in a high-energy mill. For their physicochemical characterizations, field emission gun scanning electron microscopy and analysis (FEG-SEM) and EDS, as well as X-ray diffraction analysis, were carried out. The geopolymeric compositions were tested for their mechanical strength according to curing time and temperature. The produced geopolymers showed potential for use in protective coatings for the construction industry.

Reuse of textile waste with nano reinforcement for the development of materials incorporated with nanocomposites

Mariana do Nascimento Sartori[1], Dione Pereira de Castro[1], Leonardo Gondim de Andrade Silva[1]

[1]Instituto de Pesquisas Energéticas e Nucleares (*CETER*)

e-mail: marianasartori@usp.br

The use of plastics in Brazil and the world has shown a growing demand due to their qualities, ease of obtaining, and low cost, and, consequently, produces an increase of these plastics in solid urban waste. The destination of these materials, especially in Brazil, is summarized in sending to landfills, incineration and, mechanical and chemical recycling. This study evaluates the possibility of using polyamide textile waste with elastane discarded by the textile industry, as reinforcement for the development of a polymer-clay composite, on a nanometric scale, and develop a recycling route for these materials. In that, the nanocomposite technology adds value to this material. This work used polyamides from textile waste of the industry. These materials were first processed in a compacting machine. Afterward the composites with 1, 2, and 3% in mass of Verde Clara clay/polyamide were prepared in a double screw extruder. The composites were characterized by techniques of X-ray diffraction (XRD), tensile, flexural, impact tests and thermogravimetric analysis (TGA). Results obtained were compared with the properties of the standard samples. As a conclusion of this study, it can be stated that the polyamide textile scraps with elastane can be reused forming nanocomposites with Verde Clara clay. Verde Clara clay in the proportion of 1% already confers gains in the properties of these nanocomposites.

RHEOLOGICAL AND SPECTROSCOPIC STUDIES OF MATERIALS BASED ON GLUTAMATE AND RARE EARTH IONS

Danylla Thaiana Teles de Oliveira Souza[1], Simone da Silva Simões[2], Eduardo Henrique Lago Falcão[3]

[1]Universidade Federal de Pernambuco (*DQF*) , [2]Universidade Federal de Pernambuco (*Departamento de Química Fundamental*) , [3]Universidade Federal de Pernambuco

e-mail: danyllateles@gmail.com

The synthesis of materials containing rare earth ions (RE) is a constantly evolving field in Chemistry. The use of these ions has sparked the interest of scientists due to the wide range of applications related to their electronic, magnetic, and optical properties. Monosodium glutamate (MSG) is a salt derived from glutamic acid, widely used in the food industry. It has been shown that MSG allows for the synthesis of a compound with gel-like behavior when combined with RE ions [1]. The main objective of this work is to expand on the synthesis of this material, and to perform a detailed spectroscopic study of materials based on MSG and RE ions. The methodology used follows that of previous works [1,2] carried out by our research group, which produced transparent, hygroscopic, and highly viscous materials. The 1:1 proportions between the RE (La+3 or Y+3), containing small amounts of Europium (Eu+3), and the ligand (MSG) were chosen for the structure and properties analyses. The infrared and Raman spectra presented similarities in all samples, varying minimally in the spectra of materials containing yttrium. This suggests that coordination between RE ions and MSG occurs similarly. More experiments are under way to better understand the form of interaction between the RE and the MSG. Preliminary rheological studies [2] showed that viscosity and elasticity parameters vary as external stress is applied, characterizing the material as a non-Newtonian fluid. Additional experiments will determine the correct classification of the material.

Rheological study of self-aggregated systems composedof different bile salts and lecithin

Giovana Cristina Zambuzi[1], Brenda da Silva Bega[2], Davi Siqueira da Silva de Souza[1], Vinícius Augusto Peixoto Tartare[2], Kelly Roberta Francisco[3]

[1]Federal University of Sao Carlos (*Centro de Ciências e Tecnologias para Sustentabilidade*), [2]Universidade Federal de São Carlos - Campus Araras (*Departamento de Ciências da Natureza, Matemática e Educação*), [3]Universidade Federal de São Carlos - Campus Araras (*DCNME*)

e-mail: giovanazambuzi98@hotmail.com

Through the development of self-aggregating systems, as well as the determination of the interactions involved in these systems and the understanding of their physicochemical properties, it is possible to elaborate various types of structures depending on the desired application [1]. One way to prepare these systems is by using surfactants, so it is possible to form structures with micelles, reverse micelles, lamellae or liposomes. Aiming at the formation of these structures, lecithin is a natural surfactant composed of two tails in its structure and undergoes self-aggregation in the presence of bile salts [2]. Bile salts are natural amphiphilic surfactants, produced by the liver and their main function is the solubilization of lipids [3]. Thus, bile salt/lecithin systems (sodium taurodeoxycholate (NaTDC) or sodium deoxycholate (NaDC)) in different ratios (0.2; 0.4 and 0.8 (m/m)) wereprepared. The systems were also prepared in the presence of two solutes: propylene glycol or polyethylene oxide, to analyze changes in the packing of aggregates. Dynamic light scattering (DLS), small angle X-ray scattering (SAXS) and rheology analyses were performed to determine the , shape, recombination time and breakage of the aggregates.

e-mail: matheus.varela@academico.ufpb.br

Cement is the most widely used construction material in the world. Nanomaterials are being considered worldwide as a partial filler for cement, especially in the production of high-strength and high-performance cement-based structures [1]. Although the incorporation of some nanoparticles improves the properties of cement based materials, the efficiency of dispersion still remains a significant challenge for nanometric powders. Reaching complete separation of nanoparticles in suspensions or composite matrices is ideal, however, it is difficult due to their high reactivity and aggregation owing to Vanderwall' s forces [2]. This study aims to increase the production of nano-scale metakaolin using the exfoliation method [1], as well as to evaluate its optimal dispersion content in cement matrices. To achieve nanoscale, the mineral platelets must be delaminated and exfoliated. A dispersant solution was prepared by dissolving NH_4Cl powder in distilled water, and metakaolin is added and stirred for homogeneity over 24 hours to ensure exfoliation of the clay plates, then heated and ground into a fine powder. The particles causing exfoliation must be thin and have a large surface area to maximize barrier properties. Organic ammonium chloride meets these criteria and expands the galleries of the clay, causing exfoliation. To confirm the formation of nanoplates and crystallography phase will be performed Scanning Electron Microscope (SEM) and X-Ray Diffraction (XRD). Zeta Potential (ZP) will be used to verify the suspension stability.

Simple fabrication of microfluidics system by do-it-yourself approach for metal oxide synthesis

Nicolas Moreira de Carvalho Gomes[1], Marco Aurélio Liutheviciene Cordeiro[1]

[1]Universidade Federal de São Carlos (*Departamento de Engenharia de Materiais*)

e-mail: nicolasmcg@estudante.ufscar.br

Microfluidics (MFs) is a swiftly burgeoning field that deals with the study and manipulation of fluids in small channels, typically in the range of micrometers. Owing to its design, which allows a fine tuning of fluids conditions such as temperature, mixing and reactants concentration, MFs platform can provide an auspicious route to flow synthesis of a myriad of materials. Whilst a settled platform in the synthesis of organic molecules/drugs, microfluidics is yet to fully realize its potential as a tool for the synthesis of nanostructured inorganic materials. In face of this scenario, this study aimed to provide an easy and reliable protocol for producing MFs devices for the synthesis of inorganic nanostructured particles, mainly silicon dioxide (SiO2). For this purpose, MFs devices were produced using a Do-It-Yourself (DIY) approach, which allows researchers to create MFs devices cheaply and easily using techniques like 3D printing, and soft lithography. MFs devices were produced by mold and casting process. First, molds with desired circuit/channel configuration (200-500 μm radius) were produced by stereolithography 3D printing (z resolution of 10 μm). The MFs device upper part was produced by pouring a mixture of poly(dimethylsiloxane) (PDMS) and catalyst over the negative mold, cured and then removed. This system was placed over a flat glass, closing the lower part of the MFs, and attached to an external pumping system. Nanostructured micro particles of SiO2 were produced by the controlled hydrolysis of tetramethylorthosilicate (in ethanol) by water/sodium hydroxide. The resulting particles were characterized by scanning electron microscopy, and the , distribution and microstructure correlated with synthesis temperature, flux and reagent concentration.

Sinterização de filmes cerâmicos usando Laser de CO2

Messias Zacarias Santos de Lima[1], David Vieira Sampaio[2]

[1]Universidade Federal de Alagoas (*instituto de física*) , [2]Universidade Federal de Alagoas (*Instituto de Física*)

e-mail: messias.zacarias@fis.ufal.br

Thin ceramic films are fundamental in today''s technology, with applications ranging from humidity sensors, optics, and electronics. The manufacturing process of these materials can take various forms. However, most of these processes require high-cost and complex apparatus. A simple, cheap, and easy-to-implement way is the spin-coating technique, which is based on spreading a chemical solution on the substrate as a result of high-speed rotation. After the deposition process, the film must undergo the sintering stage. This stage consists of high-temperature heat treatment and serves both for the elimination of organic matter and for the formation of a solid ceramic layer on the substrate surface. Usually, sintering is performed using a conventional resistive furnace. However, in recent years, there has been growing interest in unconventional sintering processes, such as CO2 laser sintering. Laser sintering has been applied both in the production of solid ceramic bodies and in post-fabrication treatment of ceramic films. These studies show that, in addition to the advantage of being a fast processing method with low contamination levels, laser sintering can induce modifications in the properties of these materials. Moreover, the laser processing of thin ceramic films, in addition to presenting an alternative to the conventional process, also opens up prospects for improving the characteristics of ceramic films and their applications. Therefore, based on these prospects, the present project aims to investigate the feasibility of laser sintering in thin ceramic films and its influence on the physical properties of these films.

Sol-Gel Encapsulation of Enzymes on Silica Based Supports as a Green Biocatalyst for PharmaceuticalsDegradation

Ani Vardanyan[1], Gulaim A Seisenbaeva[2]

[1]Swedish University of Agricultural Sciences (*Molecular sciences*), [2]Swedish University of Agricultural Sciences (*Molecular Sciences*)

e-mail: ani.vardanyan@slu.se

Biocatalytic degradation with the use of enzymes has gained great attention in the last years due to its advantages of high efficiency and environmental friendliness. The major drawbacks, such as low stability and non-reusability have been addressed in different studies and potential strategies were suggested to overcome these limitations. As such, immobilization on different silica based supports provides the possibility of enzyme reuse and prolonged stability in different operational conditions. Previously, a successful immobilization and subsequent removal of different pharmaceuticals, such as acetaminophen and diclofenac in presence of Cd(II) was performed in our group using laccase crosslinking on Fe_3O_4/SiO_2-DTPA hybrid nanocomposites [1]. In another approach, peroxidase enzymes were first immobilized on magnetite nanoparticles, and later encapsulated within a surface silica layer using sol-gel method. The encapsulation of enzymes enhanced their thermal stability and improved the activity over 20 consecutive cycles for 20 days at 55°C[2]. To produce cost-effective and green nanoadsorbents, in our latest work natural silicates were tested as enzyme substrates for core-shell immobilization techniques. With the natural silicate as a core and silica layer as a shell it was possible to encapsulate enzymes for removal and degradation of three different pharmaceuticals: diclofenac, carbamazepine and paracetamol. The biocatalysts demonstrated great oxidation rates for the selected pollutants. The enzyme acted differently in the three chosen supports due to their complex chemical composition which could have effect on overall enzyme activity.

STUDY OF METALS RECOVERY FROM PHOTOVOLTAIC PANELS THROUGH ACID LEACHING

Gabriel Brocchi Alves do Amaral[1], Laira Lúcia Damasceno de Oliveira[1], Filipe Alves Coelho[1], Roberta Martins da Costa Bianchi[1]

[1]Universidade São Francisco

e-mail: gamaral16@outlook.com

The photovoltaic energy is a clean and renewable way to obtain electricity, however solar panels have a lifespan of approximately 30 years, therefore, after this period they need to be correctly recycled [1]. The acid leaching is one of the techniques used in solar panels, where they are crushed into small pieces and submitted to a chemical acid treatment to dissolve the unwanted materials and separate the material of interest. The objective of this study is the recovering of metals by acid leaching. The panel went through the processes of disassembly, comminution in a knife mill, followed by a granulometric separation and finallya magnetic separation. The material was submitted to acid leaching, carried out in three stages, (i) with nitric acid 2 mol/L, (ii) with sulfuric acid 2 mol/L and (iii) with sulfuric acid 2 mol/L and hydrogen peroxide 0.3% in the ratio of 10:1, and the exposure of the material to each leaching step was performed in 30 minutes and 3 hours. Subsequently, the leachates received a solution of potassium ferrocyanide 0.5 mol/L, and a solution of potassium thiocyanate 0.1 mol/L, both of which were analyzed by spectrophotometry in the wavelength region from 250 to 1000 nm. As a result, the granulometric reduction in the mill was successful, allowing adequate reduction of plaque particles. The leachate in contact with potassium ferrocyanide formed the iron ferrocyanide complex, called Prussian Blue. Furthermore, it showed a band at 700 nm, characteristic of this complex. To confirm the presence of iron, the leachate was tested with potassium thiocyanate and the formation of an intense red solution was observed, corresponding to the complex pentaaqua(thiocyanate)iron(III) and presented a band at 480 nm, characteristic of the complex. Therefore, with the results obtained so far, it was possible to identify the $Fe3+$ ions in the panel.

e-mail: alansilvasjc@hotmail.com

Polylactic acid (PLA) is a biodegradable polymer that has remarkable properties, e.g., ease of synthesis, high processability and stability, in addition to low cost, thus being a renewable and promising alternative [1]. However, its application is still limited because it has lower mechanical resistance when compared to other engineering polymers [1]. Thus, one of the ways to improve the mechanical performance of PLA is the addition of nanoparticles that promote an increase in the nucleation density, contributing to greater crystallinity of the material [2]. Graphene oxide (GO) has excellent mechanical properties, and has shown a high potential to reinforce polymeric matrices [2]. Because it has a large amount of hydroxyl and carboxyl groups on its surface, it allows the introduction of other functional groups that help in the dispersion and interaction between reinforcement and matrix [2]. The aim of this project is to incorporate functionalized GO into a PLA matrix in order to build a nanostructured polymeric composite with improved resulting properties. GO was functionalized with diamine for subsequent formation of amide bonds through hydrogen bonds from the PLA carbonyl groups. Such interaction is responsible for the nucleation effect and consequent improvement in the crystallinity of the composite. The chemical interaction between the functional groups of the materials was observed using Fourier transform infrared spectroscopy (FTIR). The mechanical performance was evaluated by tensile strength test and dynamic-mechanical analysis (DMA). The determination of the crystallinity of the composite was obtained by X-ray diffraction analysis (XRD).

Study of the mechanical properties of high initial strength geopolymer concrete

Alisson Clay Rios da Silva[1], Bianca Mendes Almeida[1], Paulo Anderson Aranha Ferreira[2], Giovana Zagalo de França[2], Verônica Scarpini Candido[1]

[1]Universidade Federal do Pará (*Programa de Pós-graduação em Ciência e Engenharia de Materiais*) , [2]Universidade Federal do Pará (*Faculdade de Engenharia de Materiais*)

e-mail: alissonrios@ufpa.br

Through an adequate dosage of the components that constitute the geopolymer, a Geopolymer Cement Concrete (GCC) was developed, which had its characteristics compared with a Portland Cement Concrete (CCP), through the setting of some dosage parameters, such as consumption of binders, water/binder ratio and mortar content [1], [2], [3]. Mechanical tests of compression, diametrical traction, flexion traction, elastic modulus were performed, in addition to the determination of void indices and microscopic analyses. In general, the results of the mechanical characterization of the CCG showed a performance similar to the results of the CCP, with the advantage of developing greater strength at initial ages of 1 and 7 days. At the age of 7 days, the resistance result obtained was about 12% higher than that of the CCP for the same age. In the microstructural analysis of the concretes, it was possible to observe a better matrix-aggregate adhesion in GCC when compared to CCP, probably due to the high densification of the geopolymer matrix.

e-mail: tainaragomez2011@hotmail.com

Titanium-based nanotubes, TiNTs, were synthed by microwave-assisted alkaline hydrothermal method and subjected to ion exchange reaction with Er^{3+}, ErTiNT ions. The prepared samples were heat treated in an oxidizing and inert atmosphere to investigate the effects of temperature and atmosphere on the properties of these materials. In this work, optical, structural, morphological and crystallographic characterizations such as UV-Vis, PL, Raman, XRD, SEM and TEM were performed. From these characterizations, it was possible to observe that the morphology remained preserved until the temperature of 600 °C, even inthe presence of erbium oxides, which settled on the surface of the nanotubes. With the data obtained by UV-Vis, the band gap value of all samples was calculated and it was found that the variation of the diameter of sodium (Na^{+}) and erbium (Er^{3+}) ions, sodium content and heat treatment influenced the value of the band gap. The strong luminescence was influenced by the amounts of oxygen vacancies, which predominated in the samples heat treated in inert atmosphere. The presence of these defects was determined by the energy of Urbach. Through these studies, it can be suggested the use of materials exchanged with erbium, ErTiNT, in optoelectronic and photonic applications, as photoluminescent devices.

Study of the structure effect on the cloud point of RAFT produced pDMAEMA-b-pS copolymers

Vinicios Santiago Araujo[1], Fabio Herbst Florenzano[1]

[1]Escola de Engenharia de Lorena - EEL/USP (*Departamento de Engenharia de Materiais*)

e-mail: viniciussantiago7@usp.br

The raising interest in materials for sophisticated applications has driven the development of new methodologies for the production and processing of polymers. Reversible Deactivation Radical Polymerization (RDRP) is among those new concepts [1]. Such techniques allow the synthesis of tailored polymeric materials presenting narrow molecular mass distributions and compositional homogeneity. This is crucial for the study of how average molar mass and composition influence properties. Here, RAFT is used to simultaneously study the influence of aggregation state and the cloud point of PDMAEMA-b-PS copolymers. The thermoresponsive PDMAEMA macroCTA was synthesized using RAFT under GPC monitoring. The reaction presented a steadily molar mass growth up to 30240 g/mol, as expected for a RDRP synthesis. The final Mw/Mn was 1,42. The purified macroCTA was extensively characterized via FTIR and GPC. Cloud point in aqueous media was determined by UV-Vis spectroscopy at different conditions. This macroCTA is to be subsequently used for a copolymerization with styrene to generate block copolymers with different (increasing) PS content, under the exact same conditions. A simultaneous study of aggregation state via DLS and cloud point determination is intended to explore the interrelationship between aggregation and thermal behavior.

Surface free energy evaluation of doped diamond-like carbon films

Alexandre Barbosa da Silva[1], Bárbara Moraes Vicente[2], Francisco Alves Vicente[1], Bruno Borges Ramos[1], Cristiano Binder[3], Aloisio Nelmo Klein[4]

[1]Universidade Federal de Santa Catarina (*EMC*) , [2]Universidade Federal de Santa Catarina, [3]Universidade Federal de Santa Catarina (*Engenharia Mecânica*) , [4]Universidade Federal de Santa Catarina (*Departamento de Engenharia Mecânica*)

e-mail: alexandre.b.s@labmat.ufsc.br

Surface free energy (SFE) is critical for understanding adhesion and interfacial interactions in various applications. Anti-scale surfaces, for example, must be engineered to guarantee low chemical affinity with the compounds formed during thermodynamic variations that the contact fluid undergoes. Additionally, surface roughness (SR) can directly influence the wetting behavior of a material, hence, modifying the resultant SFE and playing role into adhesion of the scale. Diamond-like carbon (DLC) films have been increasingly proposed as a coating for applications that demands low adhesion of different products, by tailoring SFE. By adding doping elements, like Silicon and Fluorine, is possible to achieve different ranges of SFE. Moreover, DLC films present other interesting properties as elevated hardness, low friction coefficient and chemical inertia, allowing its application when polymers are not suitable. This study focuses on measuring SFE and SR. A 316L Stainless Steel (SS) substrate was investigated, and three coatings: DLC (reference DLC), DLC-F and DLC-Si. The substrate roughness was also varied, using a polished and a sandblasted finishing. The SFE measurements were conducted via sessile drop contact angle using water, ethylene glycol and diiodomethane as probe liquids. For the SFE measurement, 3 theories were evaluated: OWRK, Wu and Van-Oss. The results show that a decrease in total SFE for the doped-DLC coatings with sandblasted topography, compared to the SS substrate, while the coatings with polished topography showed the opposite behavior. The statistical analysis of the results indicates that, in relation to the SFE methods used, the total SFE converges to average values. When analyzing components of SFE individually a significantly variation of values was observed.

The activated carbon is characterized by being an excellent adsorbent, besides being non-toxic, and can come from renewable carbonaceous materials [1]. From these characteristics, the biomass from the mesocarp of babassu coconut was used for the synthesis of activated carbon in order to obtain a great porosity and appreciable surface area. Three parameters of synthesis were used: the variation of temperature, the form of pre-treatment and chemical activation with different proportions of potassium hydroxide (KOH), in order to obtain better physical and chemical properties and a better yield. The samples were characterized using techniques such as: Fourier Transform Infrared Spectroscopy (FTIR), Scanning Electron Microscopy (SEM), Elemental Analysis (CHNS), Zeta Potential and the surface area and porosity determined by the BET (Brunauer, Emmett, Teller) method. In order to alleviate the problems caused by textile industries, which produce a large amount of residues, which are often characterized by being carcinogenic and a eutrophication factor, which presents itself as risks to health and to the In the environment [3], activated carbon was applied in the adsorption of the cationic dye methylene blue, so that tests of kinetics and isotherm of adsorption were performed to acquire the relationships of time, concentration and adsorption capacity. About 94% of the tested dye was adsorbed by one of the samples obtained, so that the adsorption would be chemically occurring in monolayers and with a saturation time of 6 hours.

Synthesis and characterization of iron oxides and their application as inorganic pigment

Silvia Jaerger[1], Nayara Balaba[2], Felipe Leria Stefenon[2], Pedro Pablo González Borrero[2], Fauze Jacó Anaissi[2]

[1]Universidade Estadual do Centro Oeste (*Quimica*) , [2]Universidade Estadual do Centro Oeste

e-mail: sjaerger@gmail.com

Most inorganic pigments are composed of oxides, sulfides, oxyhydroxides, silicates, sulfates, or carbonates, with iron oxides being a special group of natural pigments. Iron oxides have characteristic colors such as red, yellow, brown, green, and black and have good thermal stability, chemical resistance, nanometric , non-toxic and low cost [1]. In this study, synthetic inorganic pigments (SIP) based on iron oxides were synthed by the alkaline precipitation method. The sample was left in aqueous suspension and dispersed in commercial real estate paints, white and colorless, to evaluate their behavior as a pigment. Structural characterization (XRD), composition (EDXRF), spectroscopy (UV-Vis and photoacoustic), and colorimetry were performed. The phases indexed by XRD were goethite, hematite, and magnetite [2,3]. The inorganic pigments produced showed dispersion compatibility in commercial white paint, without changing the surface coating power, and could be an alternative to produce synthetic inorganic pigments and compatible with natural inorganic pigments.

The discharge of persistent organic pollutants (POPs) from wastewater into the environment due to industrial waste is a growing concern [1]. Various methods have been employed for POP elimination, including advanced oxidation processes (AOPs), which generate highly reactive and non-selective hydroxyl radicals (·OH) that can break down pollutants into safer compounds [2]. Among AOPs, the Fenton process is widely used to generate ·OH, often with the aid of other techniques such as ultrasound (known as Sono-Fenton). Metal-Organic Frameworks (MOFs) have emerged as a promising class of heterogeneous Fenton-like catalysts due to their unique crystalline porous structure formed by metallic or clusters connected by organic ligands [3]. In this study, the MOF MIL-53 (Fe) was synthed via the solvothermal method and applied in the Sono-Fenton process to degrade organic dyes (methylene blue and methyl orange). The sample was characterized by XRD, FTIR, SEM/EDS, and TGA. XRD analysis confirmed the formation of desired MOF. The results showed that Fe-MOF is a promising catalyst for selectively removing organic dyes via the Sono-Fenton Process, with a shorter degradation time for methylene blue than for methyl orange with degradation efficiency of 97% and 95,4%, respectively.

Nanomaterials have become a symbol of great attention in the area of agriculture, due to the continuous technological advance, using nanoparticles and nanocomposites to be used in different aspects and phases of plants, such as planting, nutrition, pest control and genetic improvement (1). In this work, the synthesis of nanogels based on polyetheramine-epoxides was carried out based on literature (2,3). The influence of the amine-epoxide molar ratio on the nanoparticles formation was evaluated. The embedded of Fe ions during the nanoparticles synthesis was studied. All the nanogels obtained were characterized by techniques such as: DLS/ zeta potential, TEM and SEM. Moreover, cucumber seeds was primed with nanogel formulations to studied the shoot/root length. It was observed that the hydrodynamic diameter of the nanogels were 400 nm and 700 nm as a function of metal embedded. The nanogels presenting a negative surface charge in basic medium and slightly positive in neutral or acid medium. Preliminary results, demonstrated that the application of nanogels in Cucumber (Cucumis sativus) seeds, even without the presence of micronutrient, they show a improve of the germiation process. This work open novel perspectives of nanotechnology for agriculture purposes.

Synthesis and Characterization of $Sr_{1,75}Ca_{0.25}Fe_{1,5-x}Ni_xMo_{0,5}O_{6-\delta}$ with Doping by Mechanosynthesis and Production of Nanoparticles by Exsolution Aiming Application in Symmetrical Solid Oxide Fuel Cells

Suzane Tiemi Kawahara Shimuta[1], Daniel Zanetti de Florio[2]

e-mail: suzane.tiemi@aluno.ufabc.edu.br

Nowadays, the need to produce clean and renewable energy is increasing. Solid Oxide Fuel Cells emerge as a strong candidate, converting chemical energy into electrical energy, without the need for combustion, releasing almost no toxic substances into the environment. Symmetrical solid oxide fuel cells (SSOFCs) use the same material for both electrodes, having advantages over common cells such as reduction of difficulties in chemical and thermal compatibility between the electrodes and the electrolyte. This work presents the synthesis of $Sr_{1,75}Ca_{0.25}Fe_{1,5-x}Ni_xMo_{0,5}O_{6-\delta}$ (SCFNMO) aiming to transform CH_4 into syngas directly in the SOFC anode chamber. $Sr_2Fe_{1,5}Mo_{0,5}O_{6-\delta}$ (SFM) is promising for application in SSOFCs, as it proved to be stable in oxidation and reduction reactions [1]. To improve the characteristics of SFM, A and B sites can be doped with calcium and nickel, respectively, promoting better electronic conductivity and increasing the catalytic activity in the dry reform of CH_4. Three different compositions will be studied: $Sr_{1,75}Ca_{0.25}Fe_{1,25}Ni_{0,25}Mo_{0,5}O_{6-\delta}$, $Sr_{1,75}Ca_{0.25}FeNi_{0,5}Mo_{0,5}O_{6-\delta}$, $Sr_{1,75}Ca_{0.25}Fe_{0,75}Ni_{0,75}Mo_{0,5}O_{6-\delta}$. SCFNMO powders were synthed by chemical route (Pechini method), followed by heat treatment. After that, $Sr_{1,75}Ca_{0.25}Fe_{1,5}Mo_{0,5}O_{6-\delta}$ powders are going to be synthed by the chemical route and will be doped with NiO by mechanosynthesis, using planetary ball mills. In future developments, reduction treatments will be performed to obtain Ni nanoparticles through exsolution in the matrix and catalytic tests will be performed. Detailed characterization of the powder will be carried out by means of X-ray diffraction, simultaneous thermal analysis, dilatometry and scanning electron microscopy.

Synthesis and characterization of the β-LiAlSi2O6doped with Mn and Cu to ceramic pigment.

Thaís M. T. Nascimento[1], Ricardo Ferrari Ferraz[2], Raquel A. P. Oliveira[2] [1]UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO, [2]UNIVERSIDADE FEDERAL DO VALE DO SÃO FRANCISCO (*Ciência dos Materiais*)

e-mail: thais.muniz17@gmail.com

Ceramic pigments are considered as a group of materials that impart color (DIMITROV et al., 2017). Several colors can be found in pigments and they depend on the addition of the dopant and method of production (ZAICHUK; AMELINA, 2017). Considering the new ceramic materials, there is spodumene (LiAlSi2O6). The most common means of productionis the solid-state, but the high temperatures used, high production cost and problems in homogenization (SEDEL' NIKOVA et al., 2011) are obstacles encountered. The present work proposes the synthesis and characterization of the β-LiAlSi2O6 doped with Mn and Cu to study the relationship between the structure and color of pigments. The samples were prepared by proteic sol-gel method, using the proportion 1:0,5 of reagents:gelatin. A solution was prepared with gelatin and water at a temperature of 70 ºC and constant agitation. Then the following reagents were added: aluminum nitrate nonahydrate, lithium nitrate, silica oxide and the dopants $Mn(NO_3)_2$ and Cu(NO3)2 in different concentrations(2%, 2,5% and 3% in mass). The final solution was then heated to a temperature of 200 °C,for one hour to form a gel. The gel was dried at 100 ºC by 48 h. After drying, the xerogelwas crushed and then subjected to pre-calcination, of 700 °C by 2h. Then the samples werecalcined for two hours at 110 ºC and cooled freely. X-ray diffraction (XRD), scanning electron microscopy (SEM) and X-ray fuorescence (XRF) were performed. XRD results confirmed that the cryst structure of lattice correspondend to β-spodumene, compatible withreference ICSD 14235. SEM analysis identified polycrystalline particles of micrometric order, with irregular morphology for all samples. XRF analysis identified the elemental composition of the samples. Preliminary results show the viability of the synthesis of β-LiAlSi2O6 through the protein sol-gel method and a great potencial for obtaining ceramic pigment in different shades of blue and gray.

Synthesis and modification of deep eutectic solvents (hDES) for removal of inorganic contaminants in sewage sample

Rafaela Silva Lamarca[1], Éder Ramos Paganini[1], Nathália dos Santos Ferreira[1], Sabrina dos Santos Ferreira[1], Mario Henrique Gonzalez[1]

[1]Universidade Estadual Paulista (*Departamento de Química e Ciências Ambientais*)

e-mail: rafaela.lamarca@unesp.br

A stream of studies called Green Analytical Chemistry was initiated in recent decades with the aim of reducing or eliminating the use of toxic products for humans and the environment [1]. In this context, the deep eutectic hydrophobic solvents (hDES) has been highlighted by particularities such as biodegradability and high extraction efficiency [1]. The aim of this study was to prepare a hDES and modify it with Fe_2O_3 particles to apply it in the removal of inorganic contaminants in sewage samples. The first step involved the preparation of the hDES from a mixture of acetic acid and DL-menthol (1:1 molar ratio) under stirring at 200 rpm and heating for 15 min at 60 °C. The physical-chemistry properties of the formed solvent were obtained by density and viscosity measurement and spectroscopic characterization by ATR-FTIR mode. The interpretation of the main vibrational modes present in the FTIR spectra of the precursors and hDES showed a shift of the symmetric stretching of the carbonyl group (υ_sC=O) from 1704 to 1713 cm^{-1}, indicating the formation of hDES. The second step involved the hDES modification by the Fe_2O_3particles, prepared by coprecipitation from ions Fe^{2+} and Fe^{+3}solution in pH 9.0. Structural studies from X-Ray Diffraction confirmed the formation of maghemite (γ - Fe_2O_3) crystalline phase (PDF25-1402/ cubic, space group ($P4_32_12$), a = b = c = 8.34 Å). The morphological study of γ - Fe_2O_3 particles from Transmission Electron Microscopy showedan average distribution lower than 500 nm. The next step will focus on the use of hDES modifiers with Fe_2O_3 particles in the removal of Cd and As present in sewage samples and ICP-MS analysis.

Extensive research has demonstrated that quercetin has potential health benefits, including mitigating inflammation and oxidative stress, which are critical factors in the development of numerous chronic diseases such as cancer, heart disease, and neurodegenerative disorders. Conjugating quercetin with nanocrystals is an innovative technique with tremendous potential that improves its solubility, bioavailability, bioactivity, and therapeutic potential. Additionally, it can improve the stability of quercetin and protect it from degradation while enhancing its imaging capabilities by providing contrast in biological samples. The group has expertise in the synthesis and characterization of biocompatible nanoparticles [1] and recently of simonkolleite nanocrystals,[2] which has few works in the medical and biological area. Therefore, in this study, simonkolleite nanocrystals were conjugated with quercetin and to investigate the conjugation infrared spectroscopy, and scanning electron microscopy were used. The results confirmed the successful conjugation. Moreover, the microbiological assays revealed that the conjugated nanocrystals had significant antimicrobial activity against various microorganisms, including Gram-positive and Gram-negative bacteria as well as fungal strains. As a result, simonkolleite nanocrystals hold promise as a material for various biomedical applications due to their enhanced stability, biocompatibility and the ease of conjugation with quercetin to potential for medical applications.

The species Endopleura uchi, Humiriaceae family, native to the Amazon, is commonly known as uxi-amarelo or uxi-liso [1, 2]. This fruit has many applications in diverse areas, aiming to contribute to sustainable development. This study presents to synthesis of activated charcoal from the uxi fruit endocarp, using physical activation (calcinations temperature) and chemical activation. The uxi fruit material was collected at the Ver-o-peso fair, the pulp was removed and were used only the seeds. The seeds were dried at room temperature and after in an oven at 60 °C, they were fractionated and then taken to the millfor maceration. The samples were sieved with a granulometry of 250 mm/ · m and was chemically activated with phosphoric acid and ferric chloride. The solution was agitated for 24 h on a magnetic stirrer and after filtered for 24h. The solution was agitated for 24 h on a magnetic stirrer and filtered for 24h. After drying, the obtained material was calcined at 700 °C for 2 h. The same calcination process was carried out for in natura sample. In orderto observe porosity, morphologically characterization was carried out on these two uxi samples by SEM (Scanning Electron Microscope) and also EDS (Energy Dispersive Spectroscopy) characterization. Scanning Electron Microscopy (SEM) images indicated thepresence of pores with an average size of 1.6 μm. From the obtained material, adsorptiontests can be carried out, in order to purify water.

Synthesis of a renewable polymeric material derivedfrom glycerol to be applied as an adsorbent to dyes

Gabriel Iago dos Santos[1], Caroline Gaglieri[1], Rafael Turra Alarcon[2], Gilbert Bannach[1]

[1]Universidade Estadual Paulista (*Química*) , [2]Universidade de São Paulo

e-mail: gabriel.i.santos@unesp.br

Polymers are extensively used in the world and most of them are from non-renewable sources. Then, sustainable sources must be founded to produce these materials. Due to the interesting resulting properties, the amines are deeply used as monomers to produce polyurea, polyamides, and others [1]. Therefore, they can be used as a crosslinking agent [2] to produce biopolymers when reacted with a pre-polymer based on glycerol and maleic anhydride. In this sense, this work produced a polymeric material based on the thermal polymerization of these reactants (235 °C for 10 minutes without using catalyst). In the mid-infrared absorption analysis (MIR) was observed changes in the spectra, corroborating the occurrence of polymerization. The final polymer presented interesting adsorbent characteristics when in contact with rhodamine B, exhibiting a potential for use as a wastewater decontaminant.

e-mail: maria.souza@iqb.ufal.br

During the production of sugar and ethanol several solid products are obtained, among them, a fraction of biomass[1]. In this work, various conditions to favour the obtaining of a high surface biochar were studied, using waste biomass of the sugar and alcohol industry as raw material. After granulometric analysis, two fractions of biochar with different granulometries were purified and dopped with nitrogen by wet route for later study of the adsorption capacity and selectivity, using methylene blue and methyl orange. Granulometric analysis showed a higher proportion of carbonaceous material with diameter above 600 μm. After purification process, Thermogravimetric Analysis showed that the solids presented 2 to 3% of inorganic material. The inorganic fraction is formed mainly by silicon, probably in the form of silicon oxide. The precursor biochar with diameter above 600 μm presented a B.E.T. surface area of 482 m^2/g and a mono-modal distribution of pore with an average of 47 Å, calculated by the BJH method.

e-mail: LEDJABRITTES@GMAIL.COM

Carbon dots (C-dots) are luminescent biocompatible carbon nanoparticles, which may be obtained from several precursors, including organic molecules[1]. They have been applied as optoelectronic devices, fluorescent anti-counterfeiting inks and fluorescent probes. C-dots are promising as pH sensors due to their easy preparation, highly stable fluorescence, low toxicity and low cost[2]. Therefore, *m*-phenyldiaminedansyl (*m*-PDDS) was synthed and applied to obtain C-dots (C*m*PDDS) that were evaluated against pH variation. The m-PDDS was obtained from a nucleophilic acyl substitution reaction with dansyl chloride in the presence of triethylamine and chloroform as solvent, with 60% yield and was characterized by ^{1}H NMR, ^{13}C NMR and FTIR. Subsequently, 10 mg (0.032 mmol) of *m*-PDDS were subjected to hydrothermal synthesis with 10 mL of distilled water in a reactor at 200°C for 4 hours to obtain the C*m*PDDS, which were centrifuged at 13,000 rpm for 10 minutes and filtered through a membrane of 20 µm. The C*m*PDDS obtained exhibited a smaller than 10 nm, with an interplanar spacing of 0.23 nm, characteristic bands of S and N groups, UV-Vis bands in the region of 257 nm and the range of 281 to 447 nm of C=N and C-N, and demonstrated an excitation wavelength-independent behavior with maximum emissions at 478 nm when excited at excitation lengths of 440 nm. The fluorescence behavior of CmPDDS was evaluated against different pH values. These exhibited an OFF-ON behavior with increasing pH (2-12), demonstrating the potential to be applied as an OFF-ON pH fluorescent sensor.

Terahertz spectroscopy characterization doped n-type AlGaN thin films

Jonathas de Paula Siqueira[1], Christoph Margenfeld[2], Flávio Caldas da Cruz[1], Andreas Waag[2]

[1]Universidade Estadual de Campinas (*Departamento de Eletrônica Quântica*) , [2]Technische Universität Braunschweig

e-mail: siquejp@unicamp.br

In this study, we investigate a series of $Al_{0.67}Ga_{0.33}N$ ternary alloys with varying silicon n-type doping levels using terahertz time-domain spectroscopy (THz-TDS). We investigated the impact of silicon doping on THz response, observing a continuous absorption increase until saturation at high concentrations above $10^{19} cm^{-3}$, then a decrease resembling absorption levels of the undoped samples, indicative of a compensation regime. A similar trend was identified through specific conductivity measurements. These findings suggest that THz- TDS can determine the optimal silicon doping level for AlGaN thin films to enhance their electronic transport properties.

THERMAL PROPERTIES OF EPOXY-ACID RESINS

Geilza Alves Porto[1], Luiz Guilherme Abreu de Paula[1], Marcos Lopes Dias[1]

[1]Universidade Federal do Rio de Janeiro (*Instituto de Macromoléculas Professora Eloisa Mano*)

e-mail: geilzaporto@ima.ufrj.br

Technological advances have provided many researches to produce high performance epoxy resins to be widely applied industrially in coatings, adhesives, insulators, etc. [1]. Epoxy-based thermosetting resins can be produced by the reaction between diepoxy compounds and organic molecules, resulting in organic networks with a high mechanical strength and good thermal stability. [2]. This study aimed to evaluate the thermal properties of epoxy resins cured with different structures of carboxylic acids, citric acid (tricarboxylic acid), and sebacic acid (dicarboxylic acid). Stoichiometry of 1:1 (COOH/epoxy) molar equivalent, 130 °C for 72 hours, were used as parameters in the curing of the epoxy resin. The FT-IR spectra of the epoxy-acid resins were evaluated to verify whether there was a complete curing reaction and identify the main functional groups present in the studied samples. The thermal properties were evaluated by Differential Scanning Calorimetry (DSC) tests to verify whether there was a displacement of the glass transition temperature, and the thermal stability of the cured resins was evaluated by Thermogravimetric Analysis (TGA). Asa result, it was observed that the use of acids with different chain s influenced the variationin the final structure of the polymer and its thermal stability; the resin cured with sebacic acid, owing to its linear structure, presented lower thermal stability and glass transition than those cured with citric acid.

The investigation of contactless luminescent thermometers imposes the search for new materials with increasingly better thermometric properties, as well as its obtaining method [1]. The ease in modulating the spectroscopic properties of materials doped with lanthanide ions makes them particularly attractive for this type of application. In this work, barium titanate particles (BaTiO3) doped with Nd3+ were synthed by a new eco-friendly sol-gel route. In this route, the chelating capacity of the natural organic matter contained in river water was used to polymerize the metal solution, which is then calcined, resulting in crystalline nanoparticles. Parameters such as concentration, pH and calcination temperature were investigated during production, with the purpose of developing a simple, efficient, and low energy cost procedure. Samples with Nd3+ molar concentrations of 0.5, 1 and 3 mol% were produced. Crystallite of 22 nm was determined from XRD data using Scherrer´s equation. SEM images revealed particles in the form of overlapping plates. The technique used for the thermometric characterization of the samples was based on the peak valley intensity ratio under excitation of 800 nm. The high relative sensitivity (Sr) values of Nd-BaTiO3 particles produced indicate the potentialities of these materials for temperature detection on nanoscale. In addition, from the results of repeatability tests, it was possible to observe that this material has excellent stability in the temperature range from 303 to 373 K.

The use of biomass residues for the preparation of luminescence interference adsorbents

Karolina F. Silva[1], Raquel A. Domingues[1], Maraísa Gonçalves[1]

[1]Universidade Federal de São Paulo

e-mail: karolina.furukawa@unifesp.br

Activated carbon (AC) has been used as an adsorbent to remove contaminants, mainly due to its high surface area, pore volume, and surface functional groups. The use of biomass as precursors have been increasing due to its abundantly available, low cost, and environmental impact. In this study, were prepared ACs from sugarcane bagasse and coffee husk, impregnated with phosphoric acid in 1:1 and 1:3 (w/w) ratios, and activated by microwave oven times of 10 and 20 minutes and heating in 500 and 1000 W. The produced AC was used to remove iron and copper ions in aqueous solutions, which are luminescence interferents. The ACs were analyzed by adsorption/desorption isotherms to calculate the apparent surface area by BET equation. The AC from sugarcane bagasse prepared within 20 minutes and 1000 W has a surface area and pore volume of 1055 $m^2. g^{-1}$and 0.511 $cm^3. g^{-1}$, respectively. The AC from husk coffee obtained had the lowest time and higher heating (10 minutes and 1000 W), showing a surface area of 708 $m^2. g^{-1}$and volume total of pores of 0.619 $cm^3. g^{-1}$. Both AC prepared with higher amounts of activating agents showed the presence of mesopores. Iron and copper complexes in different concentrations were prepared for the adsorption tests, and europium and terbium lanthanide complexes were used as luminescent sensors. Firstly, adsorption experiments of iron were made with commercial AC. The final ion concentration was determined using a calibration curve (intensity ratio for $[Eu(DPA)_3]$ with added $FeCl_3$), and was observed a decrease in the luminescence intensity as a function of iron concentration. The equilibrium conditions were obtained in 24 hours, with 10 mg of AC and 10 mL of iron solution. Under these conditions, 30% and 10% were removed for the solution containing 50 and 125 $mol.L^{-1}$of iron, respectively.

The use of rate equations to model the emissions of sodium niobate nanoparticles co-doped with ytterbium and thulium ions

Jhonatas Philipe Gomes de Almeida[1], Wagner Ferreira da Silva[1], Carlos Jacinto[2]

[1]Universidade Federal de Alagoas (*Fisica*) , [2]Universidade Federal de Alagoas (*Instituto de Física*)

e-mail: jhonatasphilipe33@gmail.com

Nanoparticles (NPs) doped with rare earth ions have immense potential for various applications, including biology, medicine, and the development of solar cells. Among the diverse areas of rare earth-doped NP research, nanothermometry has gained considerable attention [1,2]. This is partly due to its relevance to biological applications, where the precise determination of local tissue temperature can be a valuable tool in the early detection of inflammation and tumors, including cancer [3]. To contribute towards the development of more efficient thermometric systems, we conducted a theoretical and computational study to investigate the key factors that affect the emissions and relative thermal sensitivity of a system (Sodium Niobate NPs) co-doped with Ytterbium and Thulium under excitation at 1064 nm. To achieve this goal, rate equations were employed to model the emissions of this system. As a result, we found that the variations in emissions with temperature were consistent with the experimental results, which validated our model. The fluorescence intensity ratio (FIR) between the emissions at 480 and 800 nm was used to calculate the relative thermal sensitivity, whose maximum value was equal to 0.7%/K at 450 K.

Superhydrophobic surfaces have the property of repelling water, these materials have interesting features, anti-corrosion, self-cleaning, anti-contamination, among others. These characteristics are important to the industry in general. Barthlott's studies [1] on the lotus effect show that a superhydrophobic surface is composed of low surface energy allied with a nano or microstructured roughness. However, many surfaces structuring processes are expensive and complex. With the motivation of decrease the cost of production and provide new routes for the production of superhydrophobic surfaces this theoretical-experimental work proposes a topographic criteria to obtain superhydrophobicity. With this objective, thin alumina films with graduated roughness were tested. The synthesis of the material was carried out through the sol-gel process, the films were deposited using dipcoting and texturized with chemical etching with boiling water. The low surface energy was achieved through the deposition of a coat of Dynasylan F881. The wetability of the films was analyzed through hysteresis and contact angle measurement and atomic force microscopy was used to characterize the topography. A theoretical equation for the contact angle for the case of heterogeneous surface wetting in terms of the slope of the structures was proposed and compared with the experimental results. The results show that we obtained nanostructured films and increase in etching time tends to increase the roughness and slope of the surfaces. The contact angle was increased with increasing etching time. It was possible to reach the static and dynamic criteria for superhydrophobicity ($\theta \geq 150°$ and $h \leq 10°$). The experimental data showed the same behavior as the theoretical equation, so it was possible to define aslope value to obtain the static criterion for superhydrophobicity, σ_SH=1,61. [1] Wi. e-mail: douglasfazafranco@gmail.com

Transparent glass-ceramics have been a subject of continuous research due to the possibility of in-situ growth of rare-earth single crystals using the glass as a host matrix [1]. Glass-ceramics based on a composition of GeO_2-$SbPO_4$-Al_2O_3-Tb_4O_7 (GSA:Tb) have been studied. This study reports the thermal, structural, morphological and spectroscopic analyses of GSA:xTb glass-ceramics, where x ranges from 0.2 to 0.7 mol% of Tb_4O_7. Differential Scanning Calorimetry (DSC), X-ray Powder Diffraction (XRD), SEM-EDS mapping and Photoluminescence (PL) spectroscopy were used for the analyses. DSC curves for all samples indicated the presence of the glass transition phenomenon and the XRD patterns of the GSA:xTb samples showed amorphous halos and crystallization peaks, confirming the vitreous nature of all glass-ceramics analyzed. XRD patterns of GSA:xTb glass-ceramics with x = 0.5, 0.6, and 0.7 mol% of Tb_4O_7 displayed diffraction peaks attributed to the crystalline phase of $TbPO_4$. The $TbPO_4$ crystals embedded in the volume of the glass-ceramics exhibited an average distribution ranging from 10-100 µm. SEM-EDS mapping of the crystal surface indicated that it is composed of P, O and Tb elements. The $TbPO_4$ crystals displayed a novel morphology and unique design resembling an "H" shape. The PL spectra of GSA:xTb showed emission bands at 491, 548, 588 and 623 nm assigned to the electronic transitions from the $^7F_6$ ground state to the excited levels ($^5D_4 \rightarrow {}^7F_6$), ($^5D_4 \rightarrow {}^7F_5$), ($^5D_4 \rightarrow {}^7F_4$) and ($^5D_4 \rightarrow {}^7F_3$), respectively. The GSA:xTb glass-ceramics have great potential for the development of new Faraday rotators for detecting magnetic fields in industrial electrical systems in the future.

This work investigates the properties of YF3 produced via microwave-assisted hydrothermal route [1]. The correlation between synthesis parameters and structural, microstructural, and optical properties was explored, to maximize the performance, while reducing the costs and the environmental impact of production. For the synthesis, the starting reagents NH4F and Y(NO3)3 were used in stoichiometric proportion. Reactions were conducted in a sealed Teflon autoclave, under microwave heating, at 140 ºC and autogenous pressure. Different soaking times were tested (1, 5, 15, 30 and 60 min). After the synthesis, the samples were washed and dried. X-ray powder diffraction (XRD) showed that YF3 crystalline phase was already obtained after 1 min of processing. The XRD peak widths vary according to the synthesis time, indicating a dependency of crystallite on the soaking time. Scanning Electron Microscopy (SEM) images presented rod-like morphology for all the samples produced. Preliminary XPS measurements revealed a dependency between oxygen content and processing time of the samples. The dependency of relative sensitivity of Nd-doped YF3on the processing parameters is currently being investigated, for application in non-contact optical nanothermometry.

Acknowledgments: The authors acknowledge CAPES, CNPq and FAPITEC for the scholarship, CMNano-UFS and LNNano for the facilities.

Submarine Umbilical Cables are complex structures which work on a critical and adverse scenario on the seabed. The Umbilicals are composed of structural layers and functional components with many different functions when connected to the subsea production system. This paper presents an accelerated ageing test method to evaluate the behavior of high density polyethylene (HDPE) material, which is applied in the outer sheath of the umbilical cables. This methodology will present a mathematical model to estimate the useful life of HDPE material in operation, using the Arrhenius Equation. The methodology consists of accelerated ageing of the HDPE samples at predefined temperatures for a determined period that will be enough to occur the decrease of mechanical properties. The specimens were stamped of the samples removed from the outer sheath of the umbilical cable after extrusion process. A quantity of 220 specimens of type V were prepared according to ASTM D-638 and they were placed in ovens with specific temperatures (100, 110 e 125°C). The test was periodically monitored through variation of the mechanical properties of the material. The results of the mechanical properties of the aged samples were compared with the results of the unaged samples, and with the correlation of the temperature versus time was possible develop a mathematical model capable of predicting the lifetime of the material. After all test performed, we confirm that the HDPE is a material with excellent mechanical strength, and according to the Arrhenius Plot, this material is considered suitable for production the outer sheath because it has durability greater than 30 years at an operational temperature of 85°C.

e-mail: priscila.maciel@ifal.edu.br

Ultra-high-performance concrete (UHPC) is a promising material for repairing rigid bridge pavements due to its dense and refined microstructure resulting from a high cement and fine materials content and low water/binder ratio. However, UHPC is prone to shrinkage cracking, especially due to autogenous shrinkage. To mitigate this, fibers are often added to improve the material''s tenacity and minimize crack propagation. Additionally, the addition of superabsorbent polymers (SAP) has been proven effective in reducing shrinkage strain in cementitious materials through internal curing [1].Both fibers and SAP complement each other in reducing the risk of shrinkage cracking in UHPC, and recent studies have investigated their combined use. This study aims to analyze recent developments in the synergistic effect of adding metallic and synthetic fibers with SAP in UHPC applied in bridge deck pavements. The research focuses on identifying knowledge gaps in the use of non-conventional fibers for pavement reinforcement. A bibliographic search conducted on ScienceDirect found that UHPC with steel fibers and SAP has been used in studies on rigid pavements. However, the use of UHPC for reinforcement and polymeric fibers is not common. High-modulus polyethylene (HMPE) is a potential alternative because of its resistance to severe environments and low weight. The combination of SAP and HMPE fibers could achieve a synergistic effect to improve the efficiency of reinforcement by reducing shrinkage and improving cement hydration. This study highlights a knowledge gap in the combined use of SAP and fibers, particularly HMPE, which could provide an innovative solution for conserving roads/bridges.

Humic Substances (SH) consist of 70% to 80% of organic matter and one of their main characteristics is the high complexation with metallic ions [1,2], promoting excellent metallic dispersion in catalytic supports. Thus, this work proposes the use of SH as complexing agents to obtain nickel anchored on alumina (Al_2O_3). The materials were synthed using a simple technique, wet impregnation in the presence and absence of SH. 5, 10 and 15% of Ni relative to alumina (m/m) were used, calcined at 700 °C, followed by characterization by thermogravimetry (TG), X-ray diffraction (XRD), Fourier transform spectroscopy (FTIR) and liquid N_2 adsorption/desorption at 77K and thermoprogrammed reduction (TPR). The materials synthed in the SH presence showed alumina in δ the γ and phase, lower nickel oxides reduction temperature and higher surface area. In preliminary tests in the methane decomposition to obtain ordered carbon and H_2, the catalysts synthed in the presence of SH showed superior catalytic activity.

Advanced ceramics, materials with exceptional properties, such as strength, high melting points and electrical insulation, stand out for their degree of innovation and their applications. The main objective of this study is linked to highlighting the positive properties of these materials in photoluminescence, a phenomenon responsible for the absorption of light in the material in a certain wavelength range, emitting light in response. The methodology employed consisted of prospecting search with specific keywords, by journals, and patents, showing that China has played an important role in the research and development of advanced materials in recent decades. Between 2012 and 2022, there was a considerable increase in investment in research in this area. Highlighting nickel tungstate, used as an example of a material with interesting photoluminescent properties, being useful in significant technological advances for understanding the fundamental principles of synthesis and processing of advanced materials, which may have important implications for other areas of research in materials science and engineering. They are widely applied, such as optoelectronic devices, displays, lighting, biomarkers and sensors. The synthesis method of these materials by precipitation is highlighted as a simple and economical way to create nanoparticles, improving their properties. Therefore, it is understood that the synthesis of advanced ceramics, have great potential in photoluminescence applications, showing a high degree of technological innovation, discovering a significant advance and interest in the study area.

Verification of non-uniform strain fields in the presence of defects in isotropic and anisotropicmaterials via digital image correlation (DIC).

Silmara Mota Cardoso[1], Jean Silva Rodrigues[1]

[1]Instituto Federal de Educação, Ciência e Tecnologia do Pará (*PPGEMAT*)

e-mail: silmra@gmail.com

High concentrations of defects can reduce a part performance, leading to its premature failure. In this way, the monitoring of defects or other types of imperfections in the materials, under deformation, contributes to the early identification of problems, preventing failures. The Digital Image Correlation (DIC) technique can provide both, the equivalent measures to conventional techniques and allow the visualization of the full-field deformation [1], which make it possible to identify defects by detecting irregular fields. A texture is applied over the reference image with spray paint and a grid is digitally created, which will be correlated in subsequent images using the correlation algorithm. This work aims to present a methodology for detecting defects through the evaluation of possible irregular strain fields and shear zones in composite specimens. Ten specimens were made according to the ASTM D-638 standard, with a polyester matrix and particulate reinforcement of red mud, which is an insoluble residue resulting from the dilution of bauxite alumina, in the Bayer process. The specimens were initially sanded and polished for subsequent texture generation by spray application, with white and black paint over the delimited area. The tensile test was carried out in the universal testing machine AROTEC WDW 100E, with a test speed of 1 mm/min. Images were captured using a CANON camera, model EOS REBEL T3i, 18 MP resolution, with a capture rate of one image per second. Preliminary results indicate that the DIC algorithm was able to generate the intended strain fields, as well as allowing to identify irregular fields that can be correlated to defects present in the material under test.
